Minor defects include wire dress, burrs, and unsatisfactory surface dress.

These defects will be referred to as solder, major, and minor, respectively, throughout the remainder of this report.

The maximum per-cent-defective allowable in a manufacturing area to assure an end product of acceptable quality can be calculated, given the basic per cent-defective allowable in the end product (Table II), and assuming a minimum regular inspection efficiency of 82%. See Table III for the maximum allowable per-cent-defective in a manufacturing area and Appendix I for the derivation of the formula for that per-cent-defective.

The final consideration in planning the master control system was the establishment of a method whereby each manufacturing area could be rated with respect to the quality requirements of the end product. Quality ratings are based on a

Fig. 2. Master rating work sheet

Procedure for calculating the master rating of a manufacturing area.

Column 1 - Area of manufacture.
Column 2 - Number of joints (complexity base) assigned to a particular unit.
Column 3 - Number of units inspected (weekly).
Column 4 - ② X ③
Column 5 - Number of solder, major, and minor defects per week as recorded from Weekly Percent-Defective Chart (FIG. 1).
Column 6 - ⑤ ÷ ④ X 100
Column 7 - Factor (constant) X ⑥. The factors (constants) used are 530, 400, and 132 for solder, major and minor defects respectively.
Column 8 - For solder, major, and minor ratings: 100-⑦. Negative values are interpreted as 0.

For overall rating: $100-\frac{\Sigma ⑦}{3}$ Negative values are interpreted as 0.

* Printed circuit cards are not soldered. A complexity number of 20 was assigned as a measure of unit complexity as related to those units whose complexity is based on the number of solder joints in the unit.
**Due to the great variations of complexity between the different types of frames, complexity figures were determined for each type of unit.

scale of 0–100 and are divided into three general categories:

100–93 = area above average
92–82 = area average
81–0 = area below average

Operational Procedure

The operational procedure covering the master control of manufacturing areas comprises the following steps:

1. Inspection results are reported on a weekly basis to the quality engineering department. This weekly chart (Fig. 1) describes each manufacturing area according to the following considerations:
   (*a*). The number of units inspected.
   (*b*). The number and description of solder defects, major defects, and minor defects found in each manufacturing area.
   (*c*). Trend lines of solder per-cent-defectives, major defect per-cent-defectives, and minor defect per-cent-defectives in relation to their respective limit lines.
2. Information accumulated on the weekly quality control chart is then transferred to the master rating work sheet (Fig. 2). Using this work sheet, quality ratings are derived for each manufacturing area. The formulas (Appendix II) used for these calculations are as follows:

$$\text{Master rating (solder)} = 100 - \frac{53{,}000}{N}\, d_s$$

$$\text{Master rating (major)} = 100 - \frac{40{,}000}{N}\, d_{ma}$$

$$\text{Master rating (minor)} = 100 - \frac{13{,}200}{N}\, d_{mi}$$

$$\text{Master rating (over-all)} = 100 - \frac{4{,}400}{N} \times (4d_s + 3d_{ma} + d_{mi})$$

where

N = predetermined base value of the manufactured unit multiplied by the number of units inspected during one week
d_s = total number of solder defects found by regular inspection procedures (for one week)
d_{ma} = total number of major defects found by regular inspection procedures (for one week)
d_{mi} = total number of minor defects found by regular inspection procedures (for one week)

Chart Displays

Quality ratings calculated according to the operational procedure described are then posted on the master rating chart for the manufacturing area (Fig. 3). This chart shows the actual per-cent-defectives of solder, major, and minor characteristics for each manufacturing area and the quality ratings given for each area. The over-all quality rating of each particular manufacturing area is displayed as a numerical value as well as in symbolic form.

Audit Control of Material in Stock

Theory

Through the proper use of audit inspection, regular inspection of the manufacturing areas can be improved which, in turn, will result in an improvement of the quality of the manufactured components. Audit inspection teams cover all inspection areas on a periodic basis to ascertain the best type and level of inspection for a given manufacturing area. Particular attention is given to areas with below-average ratings. See Fig. 3 for a typical list of areas visited. The specific objectives of the audit inspection activity are as follows:

1. To determine if the proper tools and procedures are being used by regular inspection.
2. To recommend improved methods of inspection when current methods are found to be inadequate.
3. To help determine the proper frequency of inspection.
4. To make available a written description of the condition of the completed product of a given manufacturing area.
5. To aid in determining the product characteristics most in need of inspection.

The audit inspection activity is, in effect, an additional assurance that a high level of inspection will be maintained, assuring a flow of high-quality material into stock.

The type of inspection (100% or sampling) utilized by an area visited by audit inspection personnel provides a basis for determining the quality rating of that area. This arrangement is described in the following under two separate headings: areas covered by 100% inspection, and areas covered by sampling inspection.

Areas Covered by 100% Inspection

Material going into stock is rated by audit inspection as a weighted per-cent-defective subtracted from 100. When that per-cent-defective equals the per-cent-defective allowable in the end prod-

Fig. 4. Audit inspection record

A—For manufacturing area
B—For receiving inspection areas

uct, the material is considered average and is given a numerical rating of 87, ±5. Since the range of this average rating has the same upper and lower limits as the master control chart (Fig. 3), it is possible to make comparisons between the master control and audit rating control charts in the 100% areas.

Areas Covered by Sampling Inspection

Material going into stock is rated as average when the per-cent-defective found by audit inspection personnel is the same as the per-cent-defective found by regular inspection personnel. Because of sampling risks, however, it cannot be assumed that regular inspection will always find a per-cent-defective that is equal to the per-cent-defective found by audit inspection. Accordingly, some deviation from the average value must be permitted. In this instance a ±1.5 sigma spread is allowed for sampling risks, incorporating a 0.134 probability that material which receives a rating outside the average range is, in fact, average in quality. Using the ±1.5 sigma spread, the low limit of the average range is 82, while the high limit is 92.

Ratings acquired through either method previously described are calculated on the proper work sheet and are then posted on the audit rating control chart for sampling areas. This chart shows the quality of material being passed into stock. Information appearing on the chart is displayed in two ways: 1. symbolically, as above average, average, or below average

Procedure for the Calculation of the Audit Rating of Manufacturing Areas.

Column 1 - Area of manufacture
Column 2 - Number of joints (complexity base) assigned to a particular unit.
Number of solder, major and minor defects per week as summarized from the daily Audit Inspection Record (for Manufacturing Area) (fig. 4.) The number of units inspected each week are also listed in this column.
Column 4 - Number of solder, major and minor defects (monthly totals).
Column 5 - Total number of units inspected for the month.
Column 6 - ②X⑤
Column 7 - ④÷⑥X100
Column 8 - Factor (constant)X7. The factors (constants) used are 2,400, 1,800, and 600 for solder, major, and minor defects respectively.
Column 9 - For solder, major, and minor ratings: 100 - ⑧. (Negative values are interpreted as 0.)

For overall rating: $100 - \frac{\Sigma ⑧}{3}$ (Negative values are interpreted as 0.)

Procedure for the Calculation of the Audit Rating of the Receiving Inspection (sampling) Areas.

Sample calculations performed on Appendix IV - summarized on this sheet.

* Due to the great variations of complexity between the different types of frames, complexity figures were determined for each type of unit.

** Printed circuit cards are not soldered. A complexity number of 20 was assigned as a measure of unit complexity as related to those units whose complexity is based on the number of solder joints in the unit.

K	8200	1920	1000	550	360	260	130	63

C_1 = NO. OF DEFECTIVES FOUND BY REGULAR INSPECTION.
C_2 = NO. OF DEFECTIVES FOUND BY AUDIT INSPECTION.
n = SAMPLE SIZE.
M = NO. OF LOTS INSPECTED FOR ONE MONTH.
P'MAX = MAXIMUM AQL USED (DECIMAL).

CALCULATIONS

$\Sigma T = -11.1$

$M = 10$

$$\underset{\text{(for lot 3045793)}}{t} = \frac{C_1 - C_2}{\sqrt{n}} \cdot K = \frac{0-1}{\sqrt{10}} \cdot 130 = -41$$

$$\underset{\text{(for lot 3045793)}}{T} = \Sigma t \cdot p'_{\text{max.}} = -41\,(.040) = -1.6$$

$$A_R = 87 + \frac{3.3\,\Sigma T}{\sqrt{m}} = 87 + \frac{3.3(-11.1)}{\sqrt{10}} = 75$$

Fig. 6. Sampling plan record sheet

and 2. as an actual numerical rating in relation to the limits specified.

Operational Procedure

The operational procedure for the audit control of material in stock is as follows:

1. Audit inspection personnel scrutinize all areas in which inspection operations are performed. They conduct independent inspections, using the same type of inspection techniques as are normally used in the area; e.g., 100% inspection or a specific sampling plan.

2. Findings of audit inspection are reported to quality engineering on audit inspection record forms. Information originating in manufacturing areas is recorded on the form shown in Fig. 4(A); information originating in receiving inspection areas is recorded on the form shown in Fig. 4(B).

3. Quality engineering uses the data appearing on the audit inspection record forms (Fig. 4) to evaluate material passed into stock by individual inspection areas. Depending upon the area in which the data originate (manufacturing or receiving inspection), the evaluation of individual areas is computed according to the appropriate procedures described in the following paragraphs.

The procedure for the evaluation of data originating in the manufacturing area (100% inspection) is as follows:

1. The per-cent-defective of each classification of defects (solder, major, or minor) is determined as a ratio of the number of defects to a predetermined base. (Solder defects are regarded as major defects and are classified according to a particularly stringent quality level. The predetermined base is a figure which represents the complexity of the particular unit undergoing inspection. This figure is equivalent to the base figure used for the inspection of the final product.)

2. The per-cent-defective achieved is then converted into terms of the per cent-defective desired and is weighted by a constant so that when the weighted result is subtracted from 100, a quality rating figure is achieved. See Fig. 5 for a typical audit rating work sheet.

Thus, for the quality rating of solder, major, and minor characteristics, the respective formulas are as follows:

$$\text{Solder rating} = 100 - \frac{240{,}000\, d_s}{N}$$

$$\text{Major rating} = 100 - \frac{180{,}000\, d_{ma}}{N}$$

$$\text{Minor rating} = 100 - \frac{60{,}000\, d_{mi}}{N}$$

Over-all rating (entire area combining solder, major, and minor defects in their

$$\text{proper proportion}) = 100 - \frac{20{,}000}{N} \times (4d_s + 3d_{ma} + d_{mi})$$

where

N = predetermined base of the unit involved, multiplied by the number of units inspected during the month
d_s = total number of solder defects found by audit inspection personnel (for one month)
d_{ma} = total number of major defects found by audit inspection personnel (for one month)
d_{mi} = total number of minor defects found by audit inspection personnel (for one month)

The derivations of the formulas for the manufacturing areas are shown in Appendix III.

A practical example demonstrating the operational procedure for the evaluation of data originating in the manufacturing area follows.

In a particular manufacturing area, e.g., assembly of pluggable units, audit inspection personnel examined 100 pluggable units. The examination disclosed 3 solder defects, 7 major defects, and 17 minor defects. A predetermined base value of 250 was assigned to the pluggable unit assembly area. Thus, where

$d_s = 3$

$d_{ma} = 7$

$d_{mi} = 17$

$N = 250 \times 100 = 25{,}000$

then

$$\text{Solder rating} = 100 - \frac{240{,}000(3)}{25{,}000} = 71$$

$$\text{Major rating} = 100 - \frac{180{,}000(7)}{25{,}000} = 50$$

$$\text{Minor rating} = 100 - \frac{60{,}000(17)}{25{,}000} = 59$$

Over-all rating for pluggable unit assembly

$$\text{area} = 100 - \frac{20{,}000}{25{,}000}(4.3 + 3.7 + 1.17) = 60$$

The procedure for the evaluation of data originating in receiving inspection (sampling inspection) starts with com-

A—For manufacturing areas employing 100% inspection
B—For inspection areas employing sampling inspection

putation of the quality rating of each receiving inspection area in the following manner:

1. Determine a value (t) for each acceptance quality level (AQL) used in a particular lot:

$$t=\frac{C_1-C_2}{\sqrt{N}}\times\frac{1}{p'\sqrt{p'(1-p')}}$$

where

C_1 = defects found by regular inspection
C_2 = defects found by audit inspection
N = size of sample
p' = AQL value (decimal less than 1)

The expression $1/p'\sqrt{p'(1-p')}$ has been calculated for all AQL values used, and is interpreted as the parameter K on the sampling plan work sheet. (Derivations of formulas (for receiving inspection areas) are given in Appendix IV. For a typical sampling plan record sheet see Fig. 6. See Fig. 5 for summary data of receiving inspection areas.)

2. Determine a total rating (T) for each lot:

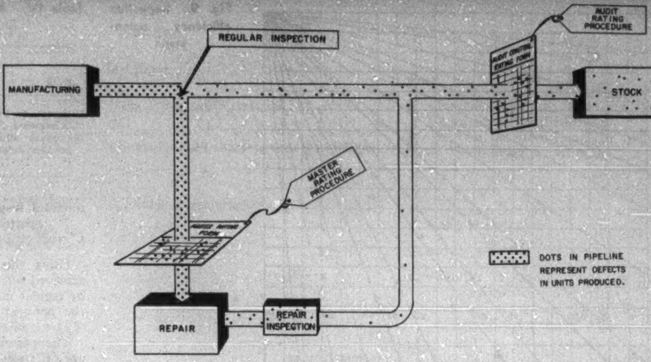
$$T=\sum_{i=1}^{j} t_i p'_{\max}$$

where

$t_i = t$ for the i^{th} AQL class
j = number of AQL classes used

3. Determine the monthly quality rating (QR)

Fig. 8. Quality assurance operation



$$QR = 87 + \frac{3.3 \sum_{e=1}^{M} T_e}{\sqrt{M}}$$

where

$T_e = T$ for the e^{th} lot

M = number of lots inspected

The constants 87 and 3.3 are chosen so that when the findings of audit inspection are equal to the findings of regular inspection, the area investigated will receive a quality rating of 87, the mid-point of the 92–82 average scale. However, if audit inspection findings indicate a 1.5 sigma increase over the number of defects found by regular inspection, the area investigated will receive a rating of 82, the lower limits of the 92–82 average scale. Similarly, a 1.5 sigma decrease in the number of defects found would cause the area to be rated 92, the upper limit of the average rating.

CHART DISPLAYS

The audit rating control chart for areas using 100% inspection (manufacturing areas) displays the per-cent-defective and quality rating for each classification of defects (solder, major, and minor) as well as the over-all rating for each manufacturing area. A typical example of the audit rating control chart for use in manufacturing areas employing 100% inspection is shown in Fig. 7(A).

The audit rating control chart for areas using sampling inspection (receiving inspection areas) displays the over-all quality rating for each inspection area. A typical example of the audit control chart for use in inspection areas employing sampling inspection is shown in Fig. 7(B).

The tell-at-a-glance information displayed on these two charts accomplishes the following results:

1. Reveals quality ratings of individual areas of inspection with respect to the ultimate requirements of those areas.
2. Calls immediate attention to areas with below-average quality ratings.
3. Specifically reveals the per-cent-defectives passed into stock; see Fig. 7(A).

Working Relation of Master Control of Manufacturing Areas and Audit Control of Material in Stock

The quality assurance procedures described in this report under master control of manufacturing areas and audit control of material in stock have a direct working relation with each other as shown in the flow diagram of Fig. 8.

Upon completion of the manufacturing operation, all units are inspected 100% by regular inspection. Any defect which is discovered by regular inspection must be repaired by manufacturing before the unit is considered acceptable as a finished product ready for audit inspection. The maximum per-cent-defective which regular inspection could find for a manufacturing area (if the end product is to fall within tolerance limits) was determined on the assumption that regular inspection would maintain a minimum efficiency of 82%. This gives a method whereby regular inspection can report on the quality or work accomplished by manufacuring and, at the same time, control the quality of the components which make up the end product. This function is described as the master control of manufacturing areas.

The next step is to check the quality of material as it enters into stock in preparation for assembly into the final system. This operation is described as the audit control of material in stock. Here audit inspection determines whether the final product meets requirements and rates the product with respect to these requirements. This rating is a numerical evaluation which reveals the quality of the product after it has been produced by manufacturing and examined by regular inspection.

Up to this point, therefore, the master control plan shows the quality of the product of the manufacturing operation, while the audit control plan gives vital information regarding the quality of material which goes into stock.

There remains now the need for determining the actual efficiency with which regular inspection is able to detect poor quality. This inspection efficiency is determined in the following manner:

$$\text{Inspection efficiency} = \frac{P_t}{P_t + P_a}$$

where

P_t = per-cent-defective found by regular inspection

P_a = per-cent-defective overlooked by regular inspection

but (from master rating plan):

$$M_r = 100 - \frac{KP_t}{C'} \text{ and } P_t = \frac{(100 - M_r)C'}{K}$$

where

M_r = master rating

K = constant = 13

C' = per-cent-defective in manufacturing which would give a rating of 87

and (from audit rating plan):

$$A_r = 100 - \frac{KP_a}{P'}$$

$$P_a = \frac{(100 - A_r)P'}{K}$$

where

A_r = audit rating

K = constant = 13

P' = per-cent-defective in the final product which would give an average rating of 87

Interpreting P_t and P_a in terms of the master rating and audit rating:

$$\frac{P_t}{P_t + P_a} = \frac{\text{Inspection}}{\text{Efficiency}} = \frac{100 - M_r}{122 - 0.22A_r - M_r}$$

For ease of interpretation, a nomo-

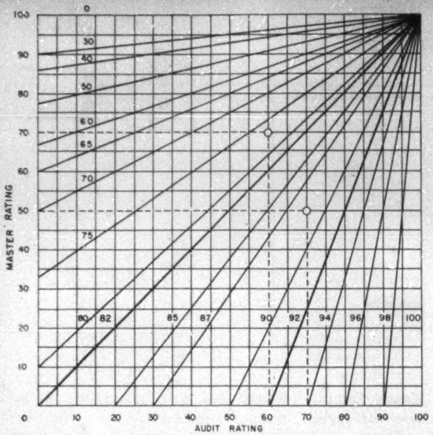


Fig. 9. Inspection efficiency nomograph

graph (Fig. 9) was constructed based on this formula. To find the efficiency of any regular inspection area it is only necessary to find the point of intersection of the master rating with the audit rating.

As with both the master control and audit control plans, ratings appear as follows:

0–82 = below average inspection efficiency
82–92 = average inspection efficiency
92–100 = above average efficiency

Conclusions

Since the adoption of this quality assurance procedure by IBM Kingston, the resulting tell-at-a-glance charts have enabled management to review the entire manufacturing process with significant improvement in ease of locating and correcting workmanship errors.

Appendix I. Derivation of Maximum Per-Cent-Defective Allowance to Manufacturing Found by Regular Inspection

For the ultimate per-cent-defectives allowable in the end product for each classification of defects, see Table II.

The fraction-defective which regular inspection finds (P_t) and the fraction-defective which is overlooked by regular inspection (P_a) are the total fraction-defective produced by manufacturing (P_m). Therefore, $P_m = P_t + P_a$.

Assume a minimum inspection efficiency of 82%. Then

$$\frac{P_t}{P_m} = 0.82$$

Therefore

$$P_m = \frac{P_t}{0.82}$$

Substitute the value of P_m into the original equation, and

$$P_t = \frac{0.82}{0.18} P_a$$

Substituting for P_a the per-cent-defective allowable in the end product for solder, major, and minor characteristics, respectively, determine the maximum per-cent-defective which regular inspection should find (at an inspection efficiency of 82%) if the end product is to meet the ultimate quality requirements. These maximum per-cent-defectives allowable (P_t) are found in Table IV.

Appendix II. Derivation of Master Rating of Manufacturing Area

Conditions or assumptions:

1. The lowest acceptable quality rating shall be 82.
2. A master rating of 82 will be given when regular inspection finds a per-cent-defective equal to the maximum per-cent-defective which regular inspection should find (P_t). See Table III.
3. A master rating of 100 is given when regular inspection finds no defects.

Formula:

$$M_r = 100 - \frac{K\,100\,\frac{d}{n}}{C'}$$

where

M_r = master rating
K = constant = 13
d = number of defects found by regular inspection

Table IV. Maximum Allowable Per-Cent-Defective

	Solder, %	Major, %	Minor, %
Ultimate quality requirements, P_a	0.0075	0.01	0.03
Maximum allowable per-cent-defective, P_t	0.034	0.045	0.136

n = total inspected; number of units inspected times the complexity base
C' = per-cent-defective considered average

Using this formula, a rating of 87 is achieved when the per-cent-defective found by regular inspection ($100\,d/n$) is equal to the per-cent-defective considered average (C').

The per-cent-defective considered average (C') was determined as that value for which a rating of 82 would be achieved when the per-cent-defective found by regular inspection ($100\,d/n$) is equal to the maximum allowable per-cent-defective (P_t).

Formula:

$$82 = 100 - \frac{13 \times P_t}{C'}$$

The C' for each P_t is found in Table V.

Table V. C′ for Each P_t

Defect Classification	P_t, %	C', %
Solder	0.034	0.0246
Major	0.045	0.0325
Minor	0.136	0.098

Using each C' as a base, the rating formulas for each type of characteristic are as follows:

$$M_r\,(\text{solder characteristics}) = 100 - \frac{13 \times 100\,\frac{d}{n}}{C'}$$

$$= 100 - \frac{1{,}300\,\frac{d}{n}}{0.0246}$$

$$= 100 - 53{,}000\,\frac{d}{n}$$

(approximately)

Therefore, in order to find the master rating for solder characteristics, it is necessary simply to multiply the per-cent-defective found by 530 and subtract this quantity from 100.

Likewise, for major and minor characteristics:

$$M_r\,(\text{major characteristics}) = 100 - 40{,}000\,\frac{d}{n}$$

$$M_r\,(\text{minor characteristics}) = 100 - 13{,}200\,\frac{d}{n}$$

(approximately)

The over-all master rating can be calculated by averaging the three values (M_r)

Vol. 7
Pt. 1
1959

Table VI. P' for Each P_e

Defect Classification	P_e, %	P', %
Solder	0.0075	0.0054
Major	0.01	0.0072
Minor	0.03	0.0216

found separately since these values have already been properly weighted.

The over-all master rating can also be calculated by combining the individual formulas and obtaining:

Over-all master rating (for any area)

$$=100-\frac{43{,}000}{n}(4d_s+3d_{ma}+d_{mi})$$

Appendix III. Derivation of Audit Rating of Manufacturing Area

Conditions or assumptions:

1. Audit inspection finds all defects missed by regular inspection.
2. The lowest rating indicating acceptable quality is 82.
3. The 82 rating is given when audit inspection finds a per-cent-defective equal to the maximum per-cent-defective allowable in the final product; i.e.,

Solder, 0.0075% defective (maximum)
Major, 0.01% defective (maximum)
Minor, 0.03% defective (maximum)

4. The 100 rating is given when audit inspections find no defects.

Formula:

$$A_r=100-\frac{K\,100\,\frac{d}{n}}{P'}\text{ for each classification of characteristics}$$

where

A_r = audit rating
K = constant = 13
d = number of defects found by audit inspection
n = sample size (number of units inspected times the complexity base)
P' = per-cent-defective considered average

Using this formula, a rating of 87 is achieved when the per-cent-defective found by audit ($100\,d/n$) is equal to the per-cent-defective considered average (P').

The per-cent-defective considered average (P') was determined as that value for which a rating of 82 would be achieved when the per-cent-defective found by audit inspection ($100\,d/n$) is equal to the maximum allowable per-cent-defective (P_e).

Formula:

$$82=100-\frac{13\cdot P_e}{P'}$$

The P' for each P_e is found in Table VI.

Using each P' as a base, the rating formula for each characteristic is as follows:

$$A_r\text{ (solder characteristics)}=100-\frac{13\times 100\,\frac{d}{n}}{P'}$$

$$=100-\frac{1{,}300\,\frac{d}{n}}{0.0054}$$

$$=100-240{,}000\,\frac{d}{n}$$

(approximately)

Therefore, in order to find the audit rating for solder characteristics, it is necessary simply to multiply the per-cent-defective found by 2,400 and subtract this quantity from 100.

Formulas for major and minor classifications of defects can be found by this procedure and are as follows:

$$A_r\text{ (major characteristics)}=100-180{,}000\,\frac{d}{n}$$

(approximately)

$$A_r\text{ (minor characteristics)}=100-60{,}000\,\frac{d}{n}$$

(approximately)

The over-all audit rating can be found by averaging the three separately found A_r values, and can also be calculated by combining the individual formulas:

$$\text{Over-all audit rating}=100-\frac{20{,}000}{n}(4d_s+3d_{ma}+d_{mi})$$

Appendix IV. Derivation of Basic Formulas for Receiving Inspection Found by Sampling Inspection Areas

Let the standard deviation, σ, be computed for that fraction defective which is considered acceptable:

$$\sigma_p=\frac{\sqrt{p'(1-p')}}{n}$$

where

p' = AQL value (fraction defective)
n = sample size

Let t be a measure of the difference between regular inspection results and audit inspection results in terms of $\sigma_{p'}$ for each AQL used, then:

$$t=\frac{p_1-p_2}{\sigma_{p'}}\times\frac{1}{p'},\text{ for the }i^{\text{th}}\text{ AQL}$$

where

p_1 = fraction defection found by regular inspection for the i^{th} AQL
p_2 = fraction defective found by audit inspection for the i^{th} AQL

$$t=\frac{\frac{C_1}{n}-\frac{C_2}{n}\sqrt{n}}{p'\sqrt{p'(1-p')}}$$

Therefore, where

C_1 = number of defects found by regular inspection for the i^{th} AQL
C_2 = number of defects found by audit inspection for the i^{th} AQL

or

$$t=\frac{C_1-C_2}{p'\sqrt{n}}\times\frac{1}{\sqrt{p'(1-p')}}$$

let

$$\frac{1}{\sqrt{p'(1-p')}}=K$$

K is calculated for each AQL used. The table of K values appears on the sampling plan work sheet of Fig. 6.

The t for the i^{th} AQL (t_i) is simply:

$$t_i=\frac{C_1-C_2}{\sqrt{n}}\times K_i$$

A T is calculated for the e^{th} lot:

$$T_e=\sum_{i=1}^{J}t_i\times P'_{\max}$$

where

J = number of AQL's involved in the inspection of the lot
$p'_{\max}$ = maximum AQL (in fraction defective) involved in the inspection of the lot

The monthly audit rating (A_r) is calculated for each inspection area:

$$A_r=87+\frac{3.3\sum_{e=1}^{M}T_e}{\sqrt{M}}$$

where

87 = arbitrary constant chosen such that when audit inspection finds a number of defects equal to the number of defects found by regular inspection, an inspection area will receive a rating of 87
3.3 = an arbitrary constant chosen such that when audit inspection finds a number of defects equivalent to 1.5 greater than regular inspection, an inspection area will receive a rating of 82
M = number of lots involved in the monthly rating for an area

Application of Telegraph Techniques in Data Transmission

A. BOGGS
NONMEMBER AIEE

J. E. BOUGHTWOOD
ASSOCIATE MEMBER AIEE

Synopsis: The impact of modernization and mechanization in business has brought drastic changes in methods and instrumentation to handle large volumes of data at high speeds. Such high-speed handling has much in common with conventional telegraphy, and telegraph techniques in principle apply to data transmission systems.

THE DEVELOPMENT of a transmission system, or systems, to handle data on a nation-wide basis must be based on a knowledge of the various types of service that may be required. It may not be possible to forsee all potential requirements at the present state of the art but some, at least, are clearly indicated. Two of these are:

1. Point-to-point service, intracity or intercity, either private wire or shared facilities.
2. Multipoint service, usually private wire, such as ticket reservation or the bookkeeping applications of large corporations.

Point-to-point service for private-wire patrons poses no serious problems and can be provided in a straightforward manner once the speed of operation has been determined. Shared facilities, such as the use of an intercity circuit by several patrons in each city, introduces some complications. Manual or automatic switching between local patron facilities and the intercity circuit must be provided. For multipoint service, where groups of patrons in different cities must be able to interchange data information, still more complicated mechanisms are required.

Carrier Equipment

For a number of years the Western Union Telegraph Company (WU) has supplied data-handling circuits engineered to fit in with its standard telegraph plant. These circuits have operated at speeds which would allow them to be assigned to narrow-band 75-baud carrier channels normally used for teleprinter service. Our planning in respect to higher-speed comprehensive data systems has been influenced by our experience with these lower-speed circuits and by consideration of transmission rates likely to represent the largest immediate use. At the same time compatibility with our present carrier telegraph plant has been preserved.

It is standard practice in WU to divide a voice band into two subbands, each capable of carrying 10 telegraph channels spaced at 150-cycle intervals. By assigning the frequency space occupied by two adjacent telegraph channels to a single data channel, a spectrum width adequate for 180 bauds is made available. This is the bit rate required by the 11-cards-per-minute IBM (International Business Machines Corporation) transceiver and represents the most common demand of commercial users of data equipment at the present time. Equipment for two such channels, one centered at 1,050 cps (cycles per second) and the other at 1,350 cps, is now available.

For rates higher than 180 bauds the entire subband spectrum, 300 cps to 1,800 cps, is utilized. The carrier equipment developed for this service is capable of operating at a maximum rate of 1,000 bauds.

At present, provision of equipment for rates higher than 1,000 bauds is not contemplated. However, circumstances are envisioned wherein it may be preferable to abandon the subband and position the 1,000 baud system in an optimum region of a whole voice band. This can be done easily with the present equipment.

Terminal Handling

The varied types of service which may be required, particularly the interconnection of a multiplicity of drops with carrier terminal legs on a half-duplex basis at a multipoint hubbing center, and the desirability of utilizing standardized equipment throughout, led to the adoption of d-c transmission on patrons' loops rather than the use of extended carrier legs. This d-c loop equipment has been engineered to accommodate a transmission speed of 1,000 bauds over balanced pairs with a steady-state loop current of 3 to 5 ma (milliamperes). Only simple *RC* equalization networks are required at this speed.

Interconnection

An important consideration in data handling by a common carrier involves the actual interconnection of the data processing equipment at the patron's location with the common carrier's equipment also at the patron's location. It is quite obvious that standards must be set if confusion is to be avoided. WU follows the standards proposed in reference 1 for the particular type of service furnished to the patron. In addition, facilities for the alternate use of the data circuit for teleprinter communication, and means for checking the common carrier transmission equipment at the patron's office, are also provided.

Data Systems

Fig. 1 illustrates one version of a point-to-point system furnishing one 180-baud data channel with New York and Chicago terminals, and one 180-baud channel via Chicago with New York and Omaha terminals. Two data channels, *A* and *B*, centered at 1,050 and 1,350 cps respectively, and six regular telegraph channels at 375, 525, 675, 825, 1,575, and 1,725 cps occupy one subband between New York and Chicago. The legs of carrier transceiver *A* are patched to the legs of transceiver *C* to establish the New York-to-Omaha connection. The Chicago-to-Omaha subband also carries eight telegraph channels, one channel at 975 and one at 1,125 replacing a 1,050-cps data channel not used in this section.

The legs of carrier transceiver *B* are patched to the legs of loop transceiver *D*. This transceiver converts the grounded polar signals of the carrier transceiver leg to a form suitable for transmission to the patron's premises over a balanced pair. Loop transceiver *E* on the patron's premises converts the received loop signals back to grounded polar form.

At the patron's office the data circuit is used to operate an 11-cards-per-minute IBM transceiver. For this particular application switching panel *F* is required to match the 10-ma legs of the loop transceiver to the higher impedance legs of the IBM set. The switching panel also permits use of the data channel for printer communication and provides means for testing the operation of the loop transceiver. Data, printer, or test function

may be selected by remote control from an operations center.

At the WU central office, meter panel *G* and associated printer form a common piece of test gear which may be corded into any data circuit. It permits printer communication either over the carrier link or over the patron's loop and also provides for metering of signals in the transceiver legs without interrupting the circuit.

Fig. 2 illustrates equipment arrangement at Chicago on a multipoint system which includes New York, Chicago, and Omaha. It is to be understood that similar equipment appears at New York and Omaha, and also that the system is not limited to three hubbing points. Three are shown here only for convenience.

Chicago patrons are connected into the network through the network repeater. Functions of other equipment shown are the same as was outlined in the point-to-point system of Fig. 1. With the arrangement shown operation is half duplex, whereby any one station communicates with all others in the network. A program-type operation, in which each station uses the circuit only on invitation to query a central computer and receive a reply, is in development.

The factor limiting transmission speed in either system is the 180-baud carrier channel. By using a full subband with delay correction and regenerative repeaters where necessary, operation at 1,000 bauds is possible throughout the entire network.

Data Transmission Equipment

All of the circuit equipments indicated on Figs. 1 and 2 have been developed and are now in limited production. The carrier transceiver for 1,000-baud operation has also been developed and prototypes tested on actual circuits. It should be of interest to cover briefly the theory of the most important items.

180-Baud Data Carrier Transceiver

This component shown in Fig. 3 is a directly modulated frequency-shift transceiver operable on a carrier frequency of 1,050 or 1,350 cps. The unit is completely transistorized and conventional frequency-shift techniques are used throughout. Marking frequency is 80 cps below and spacing frequency 80 cps above channel mid-frequency to produce a 160-cycle shift. The impedance of the sending leg is 620 ohms to ground and the impedance of the receiving leg 620 ohms to 12.5-volt polar battery.

The band-pass channel filters are conventional in design except that some departure from usual practice is introduced in the sending filter to reduce delay distortion. Adequate suppression of higher order sidebands of the wide-band frequency-shift keying requires this filter to have a pass band narrower than that required in the receiving filter. Insertion-loss and envelope-delay characteristics of the sending filter of the 1,350-cps channel are shown on Fig. 4. Both sending and receiving filters are designed to parallel with the standard 600-ohm telegraph channel filters.

Following the receiving filter, a 2-stage push-pull limiter provides 35 db (decibels) of limiting and the required power output for driving the discriminator. Two series-tuned circuits are used in the discriminator one tuned below the marking frequency and the other above the spacing frequency. The currents from the two circuits are individually rectified and differentially added to produce a polar signal output current. The signal shaping network discriminates against frequencies above 90 cps and shapes the signal for minimum distortion. Polar current from the filter drives a 2-stage directly coupled,

complementary transistor output circuit which functions as a post-detection limiter and polar output keyer. The polar output voltage is 12.5 volts through 620 ohms. Thus when the receiving leg of one channel is patched to the sending leg of another channel a current of 10 ma will flow. The unit contains rectifier supplies to provide minus 25 volts and plus and minus 12.5 volts from 115 volts a-c. When operating over a normal voice band, maximum distortion introduced by the equipment is 5% characteristic and 2% fortuitous.

1,000-Band Data Carrier Transceiver

The transceiver shown in Fig. 5 has been developed to utilize a full subband for speeds up to 1,000 bauds. Again frequency-shift operation is used with a center frequency of 1,000 cycles and a deviation of 400 cycles, the spacing and marking frequencies being 600 and 1,400 cycles respectively. To transmit at such a high modulation-frequency-to-carrier-frequency ratio over a medium which does not rigidly preserve this ratio precludes the use of direct modulation. Also, demodulation of a frequency-shift signal uses only the crossover information of the received carrier signal and so provides insufficient samples to define the modulation envelope completely.

These difficulties are avoided by using a double modulation method. The frequency-shift signal is generated at 7.5 kc and with a deviation of ±400 cycles, and passed through a band-pass filter to restrict the sideband energy to a 1,400-cycle band. The carrier signal is then modulated with an 8.5-kv carrier and the lower side band selected for transmission over the subband. The 7.5-kc carrier adequately defines the modulation envelope and this information is retained when the 7.5-kc carrier signal is translated to 1 kc for transmission. To retain this information at the 1-kc level, nonlinear circuits such as limiters must be avoided until the signal is retranslated to the 7.5-kc level. This is accomplished at the receiver by another 8.5-kc modulator, and a band-pass filter which selects the lower sideband in the 6.8- to 8.2-kc range so that the signal is restored to its original high-frequency state. At this point a delay-correction network compensates for the delay distortion introduced by the sending and receiving circuits of the transceiver. The transmission characteristics with the corrective network added are shown on Fig. 6. The signal is then limited and demodulated in the conventional manner and delivered to the receiving leg. Again both sending and receiving legs operate with 10-ma polar signals.

On a back-to-back basis the maximum characteristic distortion at speeds up to 1,000 bauds is 2% to 3%. In normal operation external networks correct the delay distortion introduced by the subband modulating equipment and carrier-system voice bands to limit the characteristic distortion to about twice the back-to-back value.

Data Loop Transceiver

For reasons previously mentioned, transmission between the central telegraph office and the patron is on a d-c or video basis and separate sending and receiving loops are employed. Transmission is accomplished by data loop transceivers located both at the central office and the patron's premises.

A block diagram of the loop transceiver is shown on Fig. 7. The transmitter phase splitter converts the 10-ma ground-return polar signal from the sending leg to a push-pull form. This signal operates an electronic switch to apply ground to one side of the loop and a negative voltage to the opposite side for a marking signal, or to reverse these conditions for a spacing signal. Since the distant end of the loop is terminated free of ground and the impedances to ground and to battery at the sending end are equal, effective suppression of extraneous interference is obtained. For this reason steady-state loop currents of 5 ma or less permit distortion-free operation at 1,000 bauds over cables having loop resistances of 5,000 ohms or more.

The receiving portion of the transceiver accepts signals from the loop and applies them to a balanced half-section *L/C* filter to reject components above 500 cycles. The signals are then equalized for amplitude and phase in a simple balanced *RC* equalizer. The equalizer is adjusted for equal output at 25-cycle and 500-cycle dotting signals. A double balanced modulator driven by a 6-kc square-wave carrier converts the d-c push-pull signal from the equalizer to a 180-degree phase-modulated carrier signal. One phase represents a marking signal and the opposite phase a spacing signal. Bias control is affected by ad-

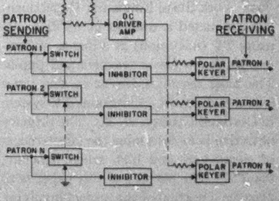

Fig. 8. Data network repeater

justing the sense and magnitude of the carrier unbalance of the modulator. The unbalance in phase with the marking or spacing carrier signal, respectively, introduces marking or spacing bias. The output transformer of the modulator provides d-c isolation of the loop circuit. The phase-modulated carrier signal is raised to a high and constant level by a limiter and then demodulated by the same 6-kc square-wave carrier to recover the d-c polar signal. Since both modulator and demodulator are operated from the same carrier source, the oscillator does not have to meet rigid stability requirements.

The demodulator output is filtered to remove carrier transients and drives a series complementary output limiter circuit to deliver 10-ma polar signals to the receiving leg.

Network Repeater

The transistorized network repeater is shown in Fig. 8 and differs somewhat from its relay equivalent currently in use for telegraph networks. Each patron's local sending loop is terminated in a p-n-p transistor switch. All these switches are series connected between ground and a d-c driver amplifier. When all the patrons' sending loops are on marking (negative battery) all the transistor switches are closed and positive signal is applied by a resistor-divider network to the driver amplifier. Under this condition the driver amplifier applies a negative signal to all the polar keyers causing them to transmit a marking signal to their individual patron's receiving loops.

A spacing signal (positive battery) from any patron's sending loop causes the associated transistor switch to open. This breaks the ground connection and the divider network applies a negative potential to the driver amplifier. As a result the driver output goes positive, causing a spacing signal to be transmitted to the individual patrons. In half-duplex service it is necessary to prevent transmission back to the patron who is sending. This is done by inhibit circuits connected between the sending and receiving side of each network stem. When a patron sends a positive spacing pulse into the network repeater, the associated inhibit circuit clamps the polar keyer in the marking condition by overriding the signal from the d-c driver amplifier. The polar keyers for the other patrons are not affected because of the isolating resistors between the driver amplifier and each keyer.

Both sending and receiving legs operate on a 10-ma polar basis. As many as 20 circuits may be hubbed with no difficulty. As a result of the transistor circuitry and because only local transmission circuits are involved, operating speeds are in no way limited by the network repeater.

Conclusions

Although our experience with these higher-speed data circuits has been limited, the indications are that they will be fully as reliable as the older low-speed circuits. In tests on average length circuits operating in IBM service at 180 bauds with full 80-column cards and with error detection, cards were rejected at an average rate of one out of 3,300 for errors.

Experience with the 1,000-baud carrier data terminal has been limited to laboratory back-to-back tests over typical subband circuits at a 600-baud speed. Indications are that error rates in the neighborhood of one character in 300,000 may be expected on normal circuits.

Our field experience has been limited to point-to-point service but all necessary transmission equipments for multipoint network service have been developed and are currently available. Multipoint system circuit layouts to meet the specific requirements of several potential users of this equipment are already in the advanced planning stage and initial installations for field trials will soon be made.

With this ground work completed we believe that the foundations have been laid for a comprehensive data handling system readily adaptable to a variety of high-speed services. This system can be realized with a minimum reorganization of present operating practices and a maximum utilization of existing facilities.

A Transmission Design for Closed Circuit Educational Television

W. L. WALL
NONMEMBER AIEE

OVER the past few years the New York State Education Department has conducted a number of experiments using TV (television) as a means of communication between teachers and pupils. The most recent endeavor in this series is a closed circuit educational TV system in Cortland County, N. Y. The primary objective is to determine the effectiveness of elementary and high school teaching via TV. The purpose of this paper is to describe a portion of the project involving the New York Telephone Company, namely, the transmission of video and audio signals from the point of origination to the schools where the information is presented to the pupils.

This educational TV system is primarily experimental in nature. It is expected that data obtained from the operation will serve as a guide in determining the future course of teaching by TV in the state of New York. An effort has been made to provide a flexible tool which will permit various types of educational experiments and thus determine which method will best convey the subject matter from teacher to pupil.

From the transmission engineer's standpoint, Cortland County appears to be an ideal location for this project. Within the city of Cortland itself are six elementary schools and one large high school, all situated in a relatively small area. Furthermore, within a radius of about 15 miles, there are numerous central school districts which will benefit by interconnection with the Cortland TV system. Two such locations, Virgil and Truxton, N. Y., are included in the initial layout shown in Fig. 1. It is interesting to note that this will permit these outlying schools

to add subjects to their curriculums which would otherwise have been impossible.

General Description

Separate video and audio signals are supplied by the customer to the telephone company patch panel; see Fig. 2. These signals modulate miniature TV transmitters and are converted to a form which is identical to that transmitted from a conventional TV station. The various TV signals plus a 77-mc (megacycle) pilot signal, which is used for regulating purposes, are combined and transmitted out over a coaxial cable distribution system to the schools where the programs are to be viewed. Signal levels along the cable are maintained within prescribed limits through the use of line amplifiers spaced on an average of 3,000 feet. Where feasible, these amplifiers are pole-mounted. However, to provide additional flexibility, an amplifier is located at most schools.

At each school location a tap-off feeding the building distribution system is provided. The distribution system within the school as well as the classroom TV receivers are the customers' responsibility. Generally, the level of the signal at the school tap-off is adequate to handle a limited number of classrooms. As the number of classrooms equipped for viewing increases, a point will be reached where distribution amplifiers will be required in order to maintain sufficient signal level at the TV sets.

It will be seen in Fig. 1 that the portion of the system within the city of Cortland forms a modified loop. With this loop or "round-robin" configuration it is possible for any of the Cortland schools to be set up as a studio and to feed programs to the other schools. Filters permit the simultaneous transmission of this program as well as any programs originating in the regular studios. The extensions to the Truxton and Virgil schools are not included in the round-robin, and therefore these locations are not available as program origination points.

In this installation only two channels were placed in service initially; ultimately a total of five channels is anticipated. The basic distribution system provides a bandwidth which extends from about 20

to 100 mc. Within this band up to six high-quality TV channels may be derived. As will be explained later, alternate channel operation is necessary because of the round-robin arrangement. This permits operation of standard channels 2, 4, and 6 in the 54- to 88-mc band. The remaining channels will be assigned to the 27- to 51-mc band for transmission from the studio to the school tap-off. At that point they will be converted to standard channels 7, 9, and 11.

Transmission Considerations

A successful TV distribution system must be capable of accepting video and audio signals at its input and delivering these signals to all the viewing locations with a minimum degradation of the information being transmitted. Furthermore, it must be capable of performing this function on a continuous basis since even short service interruptions can seriously upset a tightly planned curriculum In practice the real test is whether or not the transmission medium is capable of providing a video and audio presentation which will meet the requirements set forth for efficient teaching. To meet these requirements the Bell System has set up the following specifications for a system of this type.

1. *Radiation.* Prior to the final choice of channel assignments in any closed-circuit TV system consideration must be given to any nearby TV station in operation. In general it may be assumed that the distribution system itself can be shielded sufficiently in order to eliminate any objectionable outside signal. However, at the viewing end of the system, the problem is somewhat more difficult. A typical TV set in the classroom, even without benefit of an antenna, is likely to experience interference from any nearby station operating on the same frequency as used for the closed-circuit program. In addition, interference from certain stations operating on cochannels can also become a problem. In such cases actual tests in the classrooms are essential.

Also to be considered is radiation from the closed-circuit equipments and cables. The limits in this case are prescribed by the Federal Communications Commission. Difficulty should not be encountered with normal transmission levels and terminations.

2. *Signal Levels.* A typical amplifier output for the video carrier would be +40 dbmv where zero dbmv represents 1 millivolt across 75 ohms. Incidentally, the impedance of all the equipments and cables used in this system is a nominal 75 ohms. The levels of the audio carriers are adjusted to be 6 db lower than the video carriers. This arrangement reduces the load-carrying requirements for the amplifiers without noticeably increasing the noise level in the audio. Should carrier levels be permitted to exceed about +44 dbmv excessive overloading and intermodulation may result.

3. *Signal-to-Noise Ratios.* Tests indicate that if the minimum carrier level in the transmission system is not permitted to drop below +8 dbmv, noise will not become objectionable. Actually, once signals leave the transmission system and enter the school distribution system, levels are permitted to fall to about zero dbmv at the TV sets. At this point the carrier-to-noise ratio should not fall below 46 db. It follows that this ratio must be greater than 46 db at all points between the studio and the most distant viewing location.

Fig. 5. Line amplifier with cover removed

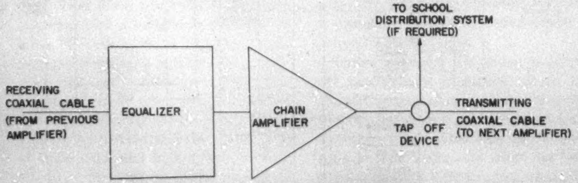

Fig. 4. Block diagram of line amplifier

4. *Cross Modulation.* This is primarily a function of: 1. the maximum number of amplifiers in tandem, 2. the maximum transmitted level, and 3. the number of channels in operation at a given time. The maximum number of amplifiers encountered between the studio and the most distant classroom in this installation is 30. Assuming normal transmission levels and a common synchronous source for all programs originating at the studio, interference should not be objectionable. With up to three channels in operation, cross modulation on the Cortland County system has not been a problem.

5. *Phase.* Since distribution is at radio frequencies, phase is not a problem in this system.

Transmission Details

At the studio location the telephone company receives video and audio signals at levels of 1 volt peak to peak and zero volume unit, which are fed via the patch panels to the transmitting terminals. These convert the signals to their assigned channels. As mentioned earlier, this terminal is actually a miniature TV transmitter which receives audio and video signals and converts them to a standard composite signal at a predetermined radio frequency in the 27- to 88-mc band. The several composite TV signals and the 77-mc pilot frequency, which is generated in the telephone company's equipment bay, are combined into a single output. This is then fed to an amplifier and transmitted out on the coaxial cable. The

Vol.
Pt. 1
1959

channelization and transmission equipment bay is shown in Fig. 3.

Amplifiers are spaced along the coaxial cable at intervals which will maintain the signal levels within the limits indicated earlier. The locations along the coaxial cable are dependent upon the following:

1. Loss in the coaxial cable at the highest operating frequency.
2. Minimum acceptable level at the input of amplifiers.
3. Additional losses due to any networks, filters, etc., inserted in amplifier sections.

Two types of amplifiers are used in this installation. One, called a line amplifier, simply provides gain which is manually adjustable from about 16 to 28 db. Figs. 4 and 5 illustrate the installations. About two thirds of the amplifiers along the cable are of this type. The remaining amplifiers are known as automatic level control stations (ALC) and are discussed in detail. Both the line amplifier and the ALC station include a chain or distributed type of amplifier unit, which is especially suited for this service since its operation is practically independent of tube failure. This feature is a basic characteristic of the chain amplifier which utilizes 12 tubes each contributing an equal amount of gain throughout the band. Loss of an individual tube has practically no effect on picture quality. With the type of cable used in this system the section preceding a line amplifier can be extended to about 4,000 feet without causing levels to drop below +8 dbmv. It is necessary to maintain a higher signal level at the input of an ALC station. Therefore the preceding section is limited to about 2,700 feet. Both the highest and lowest anticipated air temperatures must be considered in determining amplifier spacings. In summer, when cable losses are at a maximum, the levels must not be permitted to drop so low as to cause excessive noise. Conversely, in winter, when cable losses are at a minimum, the levels must not be permitted to reach a point where intermodulation and overloading become excessive. In addition to the level changes resulting from these temperature variations, a "tilting" of the coaxial loss-frequency characteristics also occurs. Therefore seasonal equalization variations become an important factor in the control of signal levels.

To assure acceptable picture quality, it is essential that the signal levels be maintained within the extremes just described. This is accomplished as follows:

1. ALC stations are provided so as to compensate for day-to-day temperature variations.
2. Seasonal gain and equalization adjustments are necessary to compensate for major temperature excursions.

At about every third amplifier location, or 81 db of cable loss at the highest operating frequency, an automatic level control station is provided; see Figs. 6 and 7 for block diagram and typical installation. The purpose of the ALC station is to compensate for cable loss variations brought about by daily changes in temperature. Following the chain amplifier unit at the ALC station is a filter which has a single input and two outputs; one output passes the entire 27- to 88-mc band on to the transmitting coaxial cable, while the other has a narrow band-pass characteristic centered around 77 mc. The latter diverts some of the 77-mc pilot signal to a specially provided amplifier which convert this signal to a d-c bias voltage of a value proportional to that of the pilot signal level. This bias voltage is used to control the gain of the chain amplifier at an ALC station. As the temperature of the cable varies, the cable loss and the pilot level fluctuate accordingly. Since the value of the bias voltage is a function of the pilot level, it is possible to maintain the amplifier output at a fairly constant value even though temperatures and cable loss may vary over a fairly wide range. A single ALC is capable of handling the level variation normally encountered in the cable section back to the preceding ALC station. With cable of the type used in this installation the distance between ALC stations or from the origination point to the first station can be extended to about 10,700 feet. The level adjustments provided by the ALC stations are flat gain in nature. Compensation for seasonal variations of the frequency and flat gain characteristics of the cable must be accomplished by manual gain adjustments and equalizer changes. This becomes necessary when the change in temperature is great enough to cause excessive loss and tilt.

Fig. 6. Block diagram of automatic level control amplifier

At school locations, a tap-off is required for feeding the distribution system. This device must not only pass all frequencies in the band used but must also provide isolation between the main line and the school room distribution system. The latter is essential since without isolation any sort of trouble in the distribution facilities not only could seriously degrade the signal for other locations but under certain conditions could cause complete failure of the system. The tap-off device used for this installation inserts a loss of less than 1 db in the main line, 10 db in the school feeder, and provides 26 db of isolation. This tap-off unit uses the directional coupler principle and requires no special equalization for the band in use.

Out-of-Studio Originations

It will be noted in Fig. 1 that an amplifier is located in most school buildings. While this does not permit utilization of maximum repeater spacings, it does provide considerable flexibility. Since this system is experimental in nature the arrangement appears well justified. This flexibility is especially desirable when out-of-studio originations are considered. With the round-robin it is possible for any school to be set up as a studio. For a typical illustration of this feature assume channel 6 and the pilot originating in the studio in the normal manner, and channel 2 originating in a special studio set up in the high school; see Fig. 8. Under normal operating conditions where all programs originate at the studio, the return leg of the cable is terminated at pole-mounted amplifier (PMA) 8. For this special case, however, it is necessary to close the loop at PMA 8 and permit passage of signals originated at the high school, but to block any signals originated in the regular studio. These latter signals upon reaching PMA 8 have already been viewed at each school location. Should they be permitted to re-enter the system a "singing" condition would exist and normal transmission would not be possible. At the high school, channel 2 would be blocked in order to prevent re-entrance and the singing condition. To prevent a build-up of circulating a noise on the closed loop, filters for blocking unused portions of the band (i.e., 27- to 54-mc, plus channels 3 and 4 and the region above channel 6) are also provided.

The blocking and passage of the various signals is accomplished through insertion of band elimination filters at the appropriate locations. Filters having characteristics sufficiently sharp to permit adjacent channel operation and still provide the necessary pass or block bands are not available. Therefore assignment must be confined to alternate channels 2, 4, and 6. Should more than three channels be required the 15- to 54-mc band will be used. Since the standard TV set does not receive these frequencies it is necessary that the telephone company provide converters at each school to translate the three subchannels to channels 7, 9, and 11, where they can be received on a conventional TV set. To date, it has not been necessary to provide subchannels for this system; however, proven equipments are available and difficulty is not expected. The original equalization design anticipated operation in the region below 54 mc and measurements indicate that this will be possible.

For any out-of-studio originations it is necessary for telephone company personnel to set up portable channelization equipment. A multichannel transmitter capable of operating on any standard TV frequency has been provided for this purpose. In addition, this unit serves as a stand-by should trouble develop in any of the regular transmitters.

Cable Facilities

The outside plant cable employed in the project is manufactured by Western Electric Company. This cable has an inner conductor of no. 9 copper wire which is supported by polyethylene disk insulators spaced about one inch apart. The outer conductor consists of a layer of copper reinforced by two layers of steel tape. Covering this assembly is a heavy jacket of black polyethylene. Fig. 9 shows the physical make-up, and Fig. 10 the electrical characteristics. This cable is intended primarily for main runs, either aerial or underground, where sharp bends are not encountered. In aerial installations it may be lashed to a specially

Vol.
Pt. 1

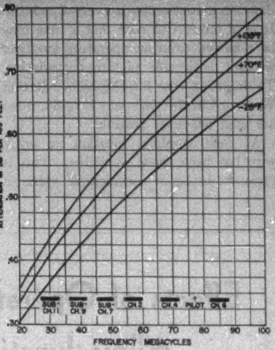

Fig. 10 (right). Attenuation characteristic for 3/8-inch air dielectric coaxial cable

provided messenger or along with an existing cable. Splicing is accomplished through the use of sleeves on both inner and outer conductors. At amplifier locations or at any point where considerable bending is required the cable is terminated in a coaxial plug which is equipped with a male N-type connector. From this point a more flexible solid dielectric cable is used. The cable used for these extensions is similar in electrical characteristics to *RG 11U* but it includes a double shield. Because of its solid dielectric the more flexible cable has greater loss than the main cable. This is not serious, however, since its use is confined to short sections.

For the main cable runs gas pressure has been provided. At amplifier locations or other points where pieces of solid dielectric cable are used a gas bypass has been installed. The gas source in Cortland is the central office dry-air system.

Equipment layouts for typical amplifier installations are shown in Figs. 5, 7, and 11. Whether mounted on a pole or in a school building the same weatherproof equipment cabinets are provided. Interconnection between the various units within the cabinet is accomplished by patch cords made of cable similar in electrical characteristics to *RG 59U* but having a double shield. Standard N-type connectors are used in all cases.

Power and Protection

From Figs. 5 and 7 it will be noted that both regulated and nonregulated 115-volt outlets are installed in the cabinets. Regulated power is provided for the system amplifiers while nonregulated power is provided for test equipment, soldering irons, etc. In a pole-mounted location, an unmetered power line covered by a fiber shield is extended from the 115-volt line overhead down to the telephone company space on the pole. This portion of the work is handled by the power company. From this point an electrician has installed conduit and extended the power conductors directly through the bottom of the amplifier cabinet. Power as well as all the coaxial cables enter the bottom of the equipment cabinets to avoid drilling in the tops which might result in water leakage. Once inside the equipment cabinet, the power leads are wired directly to a circuit breaker. For lightning and surge protection a pellet protector is bridged across the incoming power line. This protector is mounted outside the cabinet so as to prevent damage to equipment. Since power consumption at these locations is constant, meters are not required. At each PMA all equipment and grounds are bonded together. Fig. 11 shows a typical PMA.

Test Equipment

Test equipment provided for this installation included a field-strength meter, sweep generator, variable attenuator, and a radio-frequency detector. In addition, an oscilloscope, marker generator, vacuum-tube voltmeter, tube tester, and a portable TV set are available.

The sweep technique appears to be the best method for determining the general condition of the system. This method is not only useful for the initial installation work where various equalizer combinations are to be tested but also for routine maintenance including seasonal adjustments. It is, of course, necessary that the system be out of service during periods when this method is employed. For in-service testing, the levels of the TV carriers may be measured at the monitor jacks of any amplifier.

Spare Equipment

To assure reasonable service continuity, at least one spare of each type of operating equipment is provided. Provision of spares of the more common items such as line amplifiers, vacuum tubes, connectors, and equalizers is considerably more liberal than that of lesser used items. This stock of spare equipment along with test equipment is stored in a central location under direct control of the service foreman responsible for system maintenance.

Maintenance

Maintenance to date on this system has been primarily a matter of testing tubes in the chain amplifiers and it is

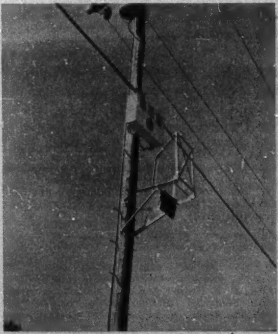

Fig. 11. Typical PMA installation

done on a routine basis every 4 months. It is of interest to note that a tube may be removed from an operating amplifier without noticeable picture degradation. To improve over-all reliability, further Western Electric Company long-life tubes are used wherever possible.

At each amplifier location an order wire has been made available. This is expected to be of considerable value in maintenance procedures. Also an alarm unit is provided at strategic locations to monitor the level of the pilot signal, which will operate should any departure exceed certain specified limits.

Conclusions

Detailed tests have been made at the studio and at the various school locations. These indicate that the pictures delivered to the classroom TV sets were essentially equivalent to those on the studio monitors. The system has been in operation since September 1958, and to date no change in picture quality has been noted. From a maintenance standpoint there have been no problems. The transmission system described in this paper meets all design requirements.

Effects of Operation of Germanium Alloy Junction Transistors Above Rated Conditions

B. C. SPRADLIN
ASSOCIATE MEMBER AIEE

As a part of the investigations and analyses performed at Battelle Memorial Institute for Remington Rand Univac, some exploratory experiments were performed at various operating conditions with type *ZJ1-501*(*4JD1A-62*) and *ZJ11-501*(*4JD1A-70*) transistors. Both of these transistors are special type *2N123* p-n-p alloy junction high-frequency switching transistors. (The primary physical difference between the *ZJ1-501* and *ZJ11-501* transistors is the thicker base region of the *ZJ1-501*.) These exploratory experiments were performed as a portion of a program directed toward the development of accelerated life test procedures for transistors.

Experimental Procedures

The two types of transistors were subjected to the operating conditions listed in Table I. Since both types of transistors are rated at 150 milliwatts power dissipation in an ambient temperature of 25 C (degrees centigrade), all the operating conditions of the experiment are above the transistors' ratings.

The transistors were operated in common-emitter circuits as shown in Fig. 1 for approximately 1,000 hours.

The base resistor was a 1% carbon-film resistor of 10,000 ohms, and the base voltage was 3 volts for all the transistors. A 5% wire-wound resistor R was employed at less than one-fifth its rated power dissipation in the collector-emitter circuit. The resistance value for this resistor and the collector-emitter voltage supply E_{ce} varied according to stress condition and transistor type.

Transistors, as is the case for any component, vary in characteristics from one unit to another. For this reason, the power-dissipation levels as shown in Table I do not signify that all of the transistors under a certain heading dissipated exactly that power. Further, the power dissipations were not held constant with time. Instead, the supply voltage in the collector-emitter circuit was set initially at the ambient temperature for the stress condition, so that the median power dissipation for the group of 20 transistors was equal to the power dissipation that was desired for each stress condition. This voltage, then, was held constant throughout the experiment. Since the collector resistor was a wire-wound type and was loaded at only a fraction of its rating, it did not change appreciably with time. Measurements of the collector-emitter power dissipation were made three times a week. The median values plotted as functions of time are shown in Figs. 2 and 3.

Room temperature measurements of the transistor parameters were made initially six times during the experiments, and after approximately 1,000 hours of operation. Checks for open or short circuits were made daily, except for week ends. Graphs of the median values of transistor parameters as functions of time are presented in Figs. 4–6. Discontinuities in these curves are caused by equipment or instrumentation malfunctioning. It appears that these effects can be neglected in considering the over-all effects of operation at the various stress conditions. Points at which the curves become vertical lines indicate that one-half or more of the transistors operating at that particular stress condition have failed.

Measurements for small-signal gain h_{fe}, d-c gain B, punch-through voltage V_{pt}, and breakdown voltage BV_{CBO} were made on an American Electronics Laboratories,

Inc., model *126H* transistor curve tracer with a Dumont model *340* oscilloscope. The small-signal gain and d-c gain were calculated from displays of the R_{22} family of curves (collector current versus collector voltage for various base currents). The collector currents were read for a collector voltage of 1 volt and 0, 2, 4, and 6 microamperes base current. The curves that are given are curves of the median values of d-c gain and small-signal gain with 6 microamperes in the base and a change of 4 to 6 microamperes base current, respectively. A typical R_{22} family of curves is shown in Fig. 7.

A typical display of curves of punch-through and breakdown voltages is shown in Fig. 8. The breakdown voltage curve was aligned with the horizontal "zero" line and a reading was made of where the curve leaves this line. Punch-through voltage was read where the punch-through curve crosses the horizontal 1-volt line, as illustrated.

Measurements of I_{CO} and I_{EO} were made with a Radio Corporation of America model *WV-84A* microammeter and a d-c transistor power supply. Configurations for these measurements are shown in Fig. 9.

Effects of Various Stress Conditions by Comparison of Mean Lives

The mean lives of the transistors for each stress condition were calculated to compare the effects of operation at the various stress conditions. These mean lives were computed from the formula

$$M=\frac{\text{aggregate operating hours}}{\text{number of failures}}$$

The mean life is the best estimate from the data available of expected life of a randomly selected transistor operated at the specified stress condition.

The failure criteria used for each type of transistor were:

ZJ1-501 (*4JD1A-62*) transistors, inoperative or I_{CO} at −65 volts greater than 200 microamperes

ZJ11-501 (*4JD1A-70*) transistors, inoperative or I_{CO} at −20 volts greater than 100 microamperes

The mean lives as a function of median power dissipation for different ambient temperatures are presented in Figs. 10(A) and 10(B). It can be seen that there appears to be an anomaly in the 100 C curves from 150 milliwatts to 200 milliwatts for both types of transistors, for these curves indicate that 150 milliwatts power dissipation is a greater stress than 200 milliwatts. It must be remembered, however, that the power dissipation shown is the median initial power dissipation for a group of 20 transistors. Because of this, the ranges around the median power dissipation overlapped between two adjacent dissipations of the factorial. To correct for this overlap, the initial power dissipations for the 60 transistors at each ambient temperature were arrayed from the least to the largest initial dissipation and then divided into three goups. The mean lives of the transistors for each of these three groups were computed and plotted as functions of the median initial power dissipation for each group. These graphs are shown in Figs. 10(C) and 10(D). It can be seen that the median initial power dissipation after arraying is approximately the same as it was before arraying. Further, the 100 C curve for the *ZJ1-501(4JD1A-62)* transistors is now more like what would be expected. The 100 C curve for the *ZJ11-501(4JD1A-70)* transistors still appears to have an anomalous portion. However, if confidence limits are placed on the mean lives and the small sample size is considered, the curves are not unreasonable.

Conclusions

The exploratory experiments used for two similar types of alloy junction transistors have been described and the median parameter variations with time have been presented in graphical form. Further, estimates of the mean lives of the transistors operating at the stress conditions of the exploratory experiments have been given. The data presented in the foregoing are not conclusive and are presented merely to show indications of the effects of operation at the various stress conditions employed in the exploratory experiments. Though not conclusive, the data do show trends of what could be expected from operation of these types of transistors at the described stress conditions.

High-Voltage Rectifier Transformer Problems

T. L. WILSON
NONMEMBER AIEE

THE FIRST successful transformer, according to the "Encyclopedia Britannica," was demonstrated in 1886 by William Staley. This places transformers among the oldest devices in the science of electrical engineering. They are so widely used today that familiarity with their operation is not confined to trained engineers. Even the average housewife is aware of their existence and the part they play in supplying electricity for household uses.

It is safe to say that millions of transformers have been manufactured for electronic applications alone. When electronic transformer sizes in excess of 1 kw are considered, this figure would probably drop to hundreds of thousands. Nevertheless, such transformers have been manufactured for high-voltage rectifier service for at least 40 years, during which time much experience has been accumulated. It would appear, therfore, that a transformer should be a very reliable device even for such rigorous service as is encountered in industrial electronic rectifiers. Experience over the past 15 years, however, indicates that this conclusion is not always justified.

Perhaps this is because the more experienced designers of high-voltage rectifier transformers have moved on to more responsible positions in their companies. Perhaps it is because new types of insulation and new philosophies of design have come into effect, or because modern competition requires much more exacting economic design than was previously demanded. In any event, the experience of several manufacturers of industrial electronic equipment indicates that transformer design technique and knowledge of transformer requirements for industrial electronic applications is lacking throughout the entire transformer industry.

The basic purpose of this paper is to describe some of the uses and abuses that high-voltage industrial transformers encounter in rectifier service and to partially analyze the reasons for some of the failures that result. In most cases, the information summarized herein was obtained from data on large transformers (5-kva and over).

Transformer failures can be divided generally into two categories, namely, failure due to coil movement and insulation failure. Coil movement is usually due to insufficient bracing of the transformer to withstand the high forces which occur with short circuits. Such short circuits are unavoidable in high-voltage rectifier service. Indeed, many designers, in order to protect delicate components elsewhere in their circuits, include devices to short-circuit the transformer deliberately, as a high-speed means of removing power from the delicate components.

Paper 59-150, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 15, 1958; made available for printing January 30, 1959.

T. L. Wilson is with the Chemetron Corporation, Louisville, Ky.

The author gratefully acknowledges the aid of his colleagues in the Girdler Process Equipment Division of Chemetron Corporation for their aid in thinking through the problems described herein, and for their critical suggestions in preparing this paper.

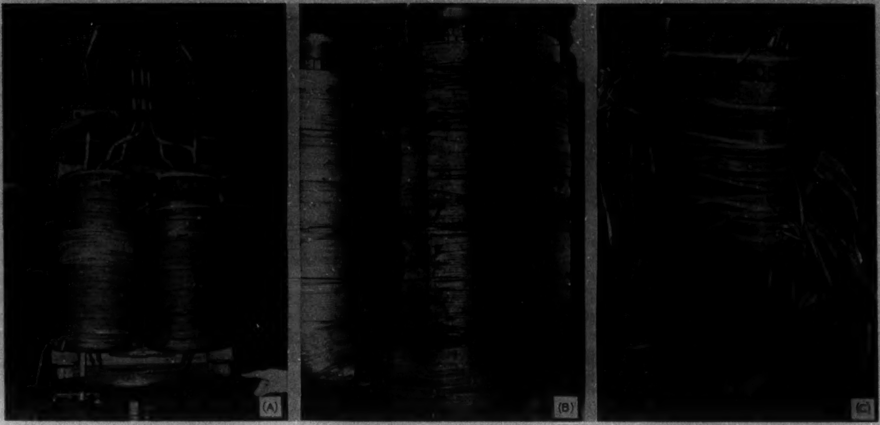

Fig. 1. Coil movement failure

A—Core and coil assembly of liquid-cooled transformer after typical failure
B—Close-up view of another failure
C—One of the coils from (A) cut to show insulation failure

1. 78
1
59

Insulation failure is due to insufficient insulation to withstand the high-voltage transients which occur in the rectifier service. These transients are sometimes troublesome in thyratron rectifiers, although they also occur in ordinary rectifiers because of several types of secondary switching in which the load on the transformer may suddenly drop to zero. In rectifier service it is possible to get a simultaneous combination of the two types of failures, as will be described later.

Coil Movement Failures

Experience has shown that failure due to coil movement has been most prevalent in liquid-cooled transformers. Because of safety considerations, the liquid is often of the noninflammable type. The use of such liquids limits the type of varnishes and insulation which may be used in a transformer.

Even in ordinary oil types, because of the desirability of including ducts for the flow of oil through the windings, impregnation cannot bind the high-voltage and low-voltage windings together as effectively as it can in air-cooled transformers. In one case, of nine 100-kva transformers, all nine had coil movement failures and were rebuilt within a 1-year service period. Obviously, such experience is expensive to the transformer manufacturer, but is even more expensive to the equipment manufacturer because of the cost of service calls and the possible loss of business due to loss of reputation for his product, and to the user because of lost production. It is surprising that transformer manufacturers apparently do not realize the amount of bracing required to withstand the rigors of a high-voltage rectifier system.

Arc Backs

Most modern rectifiers use the mercury vapor type of tube. These tubes have quite a limited operating temperature range and a rather low maximum voltage. Equipment manufacturers often include components for controlling the temperature of the condensed mercury in their rectifier tubes. They also use the tubes at considerably lower than maximum rated voltage. Even then, rectifiers are subject to arc backs, which in some industrial services may occur once a week or sometimes as infrequently as once a month; in other cases arc backs may occur more often than once a day. Some are of short duration and are self-clearing; these will give the transformer a physical force shock which can be heard as an audible thud. Other arc backs (probably more severe) are well established in the tube and exist until the power line protection system removes the source of power. These produce an even louder thud followed by a loud hum attesting to the intensity of the blow the windings have received. As will be explained later, arc backs occur very rapidly and can cause other types of failures as well as coil movement.

Crowbar

In both communication and industrial services, it is becoming a more frequent practice to include a so-called crowbar. This is a device, usually electronic, but sometimes a vacuum switch, which very rapidly applies a short circuit across the

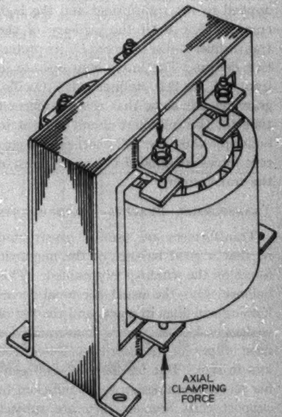

Fig. 2. Sketch of C-clamp bracing of two windings of typical transformer

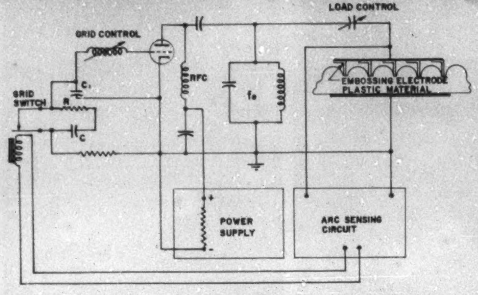

Fig. 3. Experimental oscillator circuit with arc-stopping device connected in grid circuit

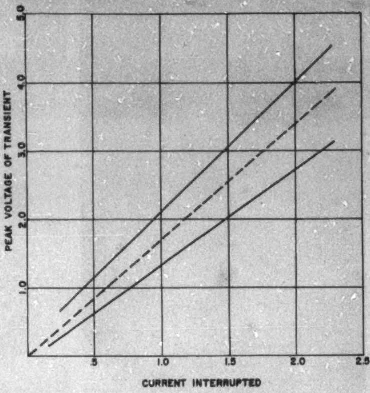

Fig. 4 (right). Curve showing maximum and minimum value of rectifier output transient versus current interrupted by means of grid switch of Fig. 3

d-c output of a rectifier system. The short circuit is applied in times varying from a few microseconds to a few milliseconds when a fault occurs in the r-f (radio-frequency) system. The purpose is to remove power from the r-f system, particularly the vacuum tubes, in as short a time as possible. In communications service crowbars must operate very rapidly so that the large quantity of energy stored in filter condensers will not be discharged into the fault which may occur in the delicate grid or seal structure of a vacuum tube. In industrial equipment, filter condensers are usually not used. Therefore, slightly slower-acting devices are satisfactory.

In either case, the short circuit is applied to the transformer and the high currents flow until the primary of the transformer is disconnected by its protective device. The latter may operate in from 17 to 200 milliseconds. Oscillogram records show that this is sufficient time for the full short-circuit current to buildup; thus the full short-circuit current forces are applied to the windings of the transformer.

TRANSFORMER BRACING REQUIREMENTS

Transformers are usually constructed so that a good balance of the magnetic forces on the windings is obtained. This balance, plus the usual frictional forces holding windings in place, and the use of wedges and other bracing, is adequate for most types of transformers below 100 kva in size. But for high-voltage rectifier service such design is not sufficient to support coils because they are subject to frequent short circuits.

Figs. 1(A) and (B) show the results of the use of normal distribution transformer construction in rectifier service. The crushing of the margin insulation and the bending of the coils are the result of very intense forces acting to move the outer windings downward. Fig. 1(C) shows the electrical failure at the point of crushing of the margin insulation.

Very strong bracing is required. Experience shows that the only successful design is one in which several screw-type clamps are placed around the periphery of the winding, squeezing the coils together in the axial direction. This "C-clamp" bracing is so designated because the windings are effectively placed in rigid, strong C-clamps. Fig. 2 shows the C-clamp type of bracing. Relative movement of the high-voltage and the low-voltage winding is prevented by the rigid clamping action.

It is well known that magnetic forces which tend to move the windings axially, can be balanced quite well (although not completely) in the original design and construction of the transformer. However, if the windings have a chance to move even slightly, this balance is rapidly destroyed. This increase in force, of course, can cause the poorly braced winding to move more on the next short-circuit blow and the additional motion causes further net force until a runaway condition is obtained. The resulting force is terrific, as from a sledge hammer, and completely crushes the margin insulation of the transformers. C-clamp or other adequate bracing, if properly applied to a well-balanced design, will prevent that first movement of the coils and thus prevent the destruction of the original force balance.

Table I. Results of Varying R-C Network Capacity

Capacitance, Microfarads	Maximum E, Centimeters	Minimum E, Centimeters	Maximum Time, Milliseconds	Minimum Time, Milliseconds
12	4.0	3.2	50	44
4	3.8	3.0	26	22
1.0	4.2	3.4	15	12.4
0.25	4.2	2.9	13.6	11.0
0.1	4.3	3.2	12.2	10.0

To emphasize, adequate bracing must be included in high-voltage rectifier transformers. It does not add appreciably to the cost of manufacture of the transformer, inasmuch as the clamps, for example, are simple devices, usually welded to the frame of the transformer. When one considers the cost of a transformer failure, not only to the supplier but to the equipment manufacturer and his customer, the investment in adequate bracing is very well justified. In the author's opinion, regardless of how small the kva of a transformer, particularly for liquid-cooled rectifier transformers, the C-clamp type of bracing should be specified and used in every case.

Insulation Failure

There are several characteristics of rectifiers which can lead to insulation failure in the transformers used with them. Some of these are perhaps more frequently encountered in industrial equipment than in communication equipment, but they all arise from the well-known characteristic of inductances in which a sudden interruption of current will cause a high voltage to appear across the terminals. This voltage can easily be destructively high and will not necessarily be evenly distributed throughout a given inductance such as a transformer winding.

Arc Interrupters

There are several ways in which the current flowing in a transformer can be interrupted rapidly. A rather common device in some applications of dielectric heating is one for rapidly extinguishing arcs which can occur in intricate electrode systems. For example, in applications of sealing plastic materials together, such as in the manufacture of interior trim panels for automobiles, a rather intricate decorative pattern is embossed into the plastic material. The dies for forming this pattern are often complex and may require many man-hours to construct. In this application they are energized while under heavy pressure with the high-frequency high voltage to accomplish the sealing and embossing.

If the plastic material has a defect, such as a small metallic inclusion, or if for some reason a high-voltage transient occurs, an arc may form between the embossing electrodes which would damage them. To avoid this, protective devices are included which will very rapidly stop the oscillation in the generator. The stopping time ranges from microseconds to a few milliseconds but the current interruption occurs in several microseconds in any case, (i.e., di/dt is high). Very often these devices, by one means or another, apply high voltage to the grid of the oscillator tube. Experience shows that, regardless of the rate of build-up of this voltage, the oscillation dies out due to a characteristic inherent in the r-f generator and this decay is very rapid. Fig. 3 shows a typical oscillator circuit in which a high-speed vacuum switch has been placed in the grid circuit. Opening this switch causes oscillations to stop because of charging of condenser C_1. In an attempt to slow down the rate of cessation of oscillation, a series R-C (resistance-capacitance) network was placed across the vacuum switch.

Table I shows the results of varying the capacity of the R-C network shown in Fig. 3. The maximum and minimum E is the deflection of the oscilloscope in centimeters, but is proportional to the magnitude of the transient. The time figures show the interval from the instant the switch is energized until oscillation is stopped. Perusal of the table indicates that, regardless of the amount of the capacity in the suppression network, the value of peak transient voltage is essentially the same. Since the load on the oscillator was constant for these tests, this indicates that the rate of change of direct current at cutoff time is constant for all values of C. However, the time of operation of the protective system is greatly increased by increasing the suppression capacity. This effect is undesirable as the object of the device is to stop oscillations as rapidly as possible.

Thus, when an arc-stopping device is used, the current in the plate transformer is suddenly interrupted. A high-voltage transient is generated, the magnitude of which depends primarily on the value of the current which was interrupted. Curves have been taken which indicate this proportionality; see Fig. 4. The two lines indicate the maximum and the minimum transients read in a series of 100 tests for each point. The dashed-line curve, which is approximately the median line, was drawn through the origin to indicate the linearity of the curve.

Fig. 5(A) illustrates typical transients at the d-c output of the rectifier when the load current is interrupted by the arc-stopping device. The transients are very similar excepting the magnitude only, which is proportional to the current interrupted as indicated in Fig. 4.

The shape of the high-voltage transient generated usually does not have an extremely fast rise time, 30 μsec (microseconds) or so, and unless the interruption occurs at abnormally high currents such as might occur in an overload, the transient is not particularly damaging to a transformer. However, such devices often operate when an abnormal current is flowing and this can cause very high voltage to occur between individual turns in a given transformer. It should be remembered that since the current in a transformer is everywhere the same, the transient voltage is induced in each turn in accordance with the effective inductance of that turn. Thus it is entirely possible, because of the relatively slow rise time of this type of transient, to have excessive voltages occur between each turn throughout the entire winding of the transformer. As a result, and probably because of the usual practice of increasing the insulation of end turns, failure often occurs in turns near the center of the winding rather than near the terminals. There is a corollary effect of this type of transient, described in the following section, which can be exceedingly damaging of the transformer insulation.

In communications, similar high-speed devices are sometimes used to extinguish arcs which may occur in r-f transmission line systems due to voltages induced by lightning surges. It is probable that in such cases the d-c filter used to smooth the ripple of rectification sufficiently isolates the plate transformer from the rapid interruption of current.

Another cause of current interruption in a secondary of a rectifier transformer is known as "ion starvation." Hull and Elder[1] (and Steiner and Strecker in an unpublished paper) describe this phenomenon which can occur when a soft tube rectifier is called upon to pass more

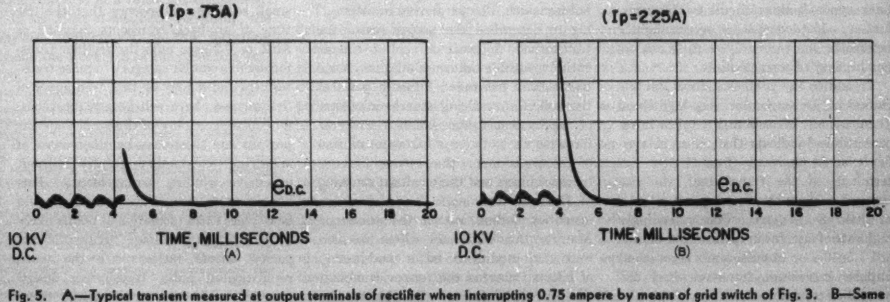

Fig. 5. A—Typical transient measured at output terminals of rectifier when interrupting 0.75 ampere by means of grid switch of Fig. 3. B—Same as (A) except current interrupted 2.25 amperes

current than there are ions available to carry the current. Normally, under rated temperature conditions, the ion starvation point of a rectifier is considerably higher than the short-circuit current of a transformer. Ion starvation cannot occur under these desirable conditions and perhaps this explains why it is a little known phenomenon. However, in industrial equipments, where less attention is given to rectifier temperature by the user of the equipment, it is quite possible to have ion starvation occur because of cold rectifier tubes.

Ion starvation occurs when magnetic forces due to heavy current flow cause the ions to leave momentarily the normal current path, so that the current is interrupted in not more than a few microseconds. After interruption, the ion starvation disappears and then ions are available for carrying current once more. If the short circuit is still present, as is usually the case, ion starvation may occur again. This may recur many times before the protective circuit-breaker equipment can operate. Thus, when ion starvation occurs, a transformer may receive many closely spaced interruptions of secondary current. This induces very high-speed very-high-voltage transients within the transformer windings.

Combination Insulation and Coil Movement Failures

Inasmuch as insulation failure is often caused by interruption of current and the coil movement failure by short-circuit currents, it would seem incompatible to have a combination failure. However, in rectifier services these two failures can occur simultaneously. When a high-voltage transient is caused as by interruption of current flowing from a rectifier, the high-voltage transient induced in the transformer is applied to the rectifier tubes, often causing an arc back. This arc back applies a short circuit to the transformer. The overvoltage occurs slightly before the short circuit, but both can occur because of a single fault.

To add to the problems, short circuits caused by arc backs are very-high-speed phenomena. Measurements taken in recent studies[2] indicate that, when a rectifier tube is physically located near the terminals of the transformer, the rise time of a short-circuit transient can be as little as 0.2 μsec. This exceedingly high rate of rise, far in excess of the standard 1.5x40-μsec impulse wave from usual impulse generators, can cause very abnormal distribution of voltages within the windings of a transformer.

As previously mentioned, the induced voltage transient, due to interruption of current in the secondary of the transformer, is quite evenly distributed throughout the winding because of its relatively slow rise time. In contrast to this, the rapid arc back of the rectifier tube effectively connects together the two ends of the transformer winding. Since this is equivalent to a steep wavefront negative impulse at the terminals of the transformer, the distribution of voltage due to this impulse is not uniform unless special precautions are taken in the design of the transformer.[2]

The studies made recently show that, in a high-voltage winding which was constructed in 16 parts with taps brought out to measure part voltages, the maximum voltage appeared across the first section and was equal to 36% of the total peak induced voltage across the whole coil. As this wave progressed through the transformer, the voltage across other portions was less, but still high. In several interior parts of the winding the voltage was as much as 25% of the total peak induced voltage. Thus, instead of the normal one sixteenth of the terminal voltage, this section received one fourth of the total terminal voltage which was four times its normal voltage.

Furthermore, since an arc back is most likely to occur when an abnormally high voltage is placed on the rectifier tube, as can be done when the load current on the transformer is suddenly interrupted, it is easily possible for the four-times-normal voltage to reach eight or twelve times normal. This much voltage applied across an interior section of a total winding which, in normal transformer design, is not usually insulated for high transient voltages, can easily destroy the insulation. This may explain why many failures occur in interior parts of the winding.

It is probably this combination type of failure which is so perplexing in attempting to determine the proper reason for transformer failures. It is, of course, entirely possible that once a liquid-cooled transformer has failed between parts of the coil, the resulting severe unbalance of mechanical forces causes the transformer coils to move. Likewise, motion of the transformer, due to many sledge hammer blows and the resultant crushing of the end turn insulation, may cause insulation failure within the windings. Many of the failures the writer has seen were attributed to the latter combination of effects, whereas the former combination was probably as responsible for the actual failure.

Some Solutions to the Problems

Solutions to the foregoing problems will be found in co-operative actions of both the transformer manufacturer and the equipment designer. There are contributions which each can make but neither can solve the problems alone.

In the case of coil movement, bracing of the transformer, as mentioned earlier is the best solution. This is primarily the responsibility of the transformer designer. The equipment designer can help by using a high-speed circuit breaker and by including some form of current limitation. Both have been used in equipments and have proved advantageous. Neither will replace adequate bracing of the transformer during its manufacture.

High-speed circuit breakers are limited as to how fast they will remove a short circuit. A modern circuit breaker is considered to be high-speed if it operates between 1 and 2 cycles. This is between 17 and 34 milliseconds. Oscillograms indicate that the short-circuit current in a transformer supplying a 3-phase rectifier will reach its maximum value well before one cycle. Therefore, while a high-speed circuit breaker cuts the duration of an applied short circuit, it cannot cut the intensity of the force.

Current limitation is useful, particularly for very stiff power lines. However, this adds regulation problems, usually minor but not always, and it also adds transient problems during current interruption. Likewise, the expense of current limitation devices is considerable and in excess of the cost of adequate bracing within the transformer.

High-speed high-voltage transients require considerable care in the design of the transformer to ensure that the distributed capacity of the winding(s) is such that even very high-speed transients will be distributed throughout the entire winding rather than piling up on small sections. Discovery that the rise time of arc-back transients may be as little as 0.2 μsec puts the rectifier transformer in a similar category to pulse transformers and it may be that techniques of design used there will be advantageous. Of course, economy of design is very important and there may be other ways of achieving satisfactory results without expensive winding arrangements. Perhaps a more economical solution would be to place extra insulation at points likely to receive extra voltage because of capacity effects, rather than the more sophisticated pulse transformer design techniques. It may prove equally effective in stopping the failures.

The equipment designer can help to increase the rise time of the arc-back transients by including a little inductance between the transformer terminals and the rectifier tubes. Spacing the leads widely, use of inductive resistors in the plates of the rectifier tubes, etc., will help to reduce the rise time. If the rise time can be kept to more reasonable values the transformer designer's problem is eased.

Several types of transient suppression devices are available. Thyrite or other nonlinear surge resistor suppressors may be connected across the terminals. In practical cases these may so reduce the transient that the terminal voltage does not exceed twice normal. *R-C* networks may also help, as will protective gaps. In many cases these devices are not adequate in high-voltage rectifiers because of the necessity of using the tubes closer to their maximum ratings than practical transient suppression will permit.

It is obvious that transient suppression means which are connected to the terminals of the transformer may not ensure adequate suppression of transients throughout the windings of the transformer. It is only the terminals of the transformer that are available to the equipment designer. The transformer designer may be able to include suppression to advantage, within the windings.

It is believed that adequate understanding of the various phenomena which may occur in a transformer applied to high-voltage rectifier service is essential to the best solution of the over-all design problems. These should be studied in detail by the designers both of transformers and of equipment. Co-operative efforts on the part of both are required to obtain the optimum in cost reduction without sacrificing reliability.

Design of a Vertical Magnetic Recording Head with Large-Scale Models

J. T. SMITH
NONMEMBER AIEE

Synopsis: A technique is described to aid in the design of magnetic recording heads. Large-scale models are used for the experimental optimization of recording head designs. To illustrate this technique, appropriate scaling factors are derived and then applied to the design of a vertical recording head.

IT IS WELL KNOWN that small-scale models of motors, transformers, and other electrical components are used to aid in design. These small models are advantageous in that certain parameters can be varied at a relatively low cost, when compared to the cost of varying the same function in a full-sized component.

In the field of magnetic recording, the physical dimensions of the recording heads, the thickness of the recording surfaces, and the gaps between the head and the surfaces are very small. For example, some of the ring-type heads have slots which are only a few microinches wide. These heads require many special techniques in their fabrication. As a direct consequence of this, to change one of the parameters in the recording head while holding all other variables constant is a difficult and expensive procedure. In this paper large-scale models of recording heads are used to relax the precision of machining required for studying the effect of several variables upon the resolution and amplitude of magnetically recorded signals.

The space covered by the magnetic field from a recording head is directly proportional to the resolution of the head. Hence it is desirable to have a linear increase of all lengths in a scaled model to produce a corresponding linear increase in the space covered by the magnetic field. Scaling factors are presented in the paper which will produce this point-by-point correspondence between the size of the magnetic field and the size of the head. These scaling factors are then applied to a vertical recording head having a particular structure. The technique is not limited to this structure but can be used upon any type of recording head. Emphasis is placed upon the ease with which the method may be used to obtain much useful information concerning the distribution of the magnetic fields around small objects.

The application of this method to a particular recording head is not done to show any advantages of this kind of recording over others; rather, it was felt that a successful application of the method presented in detail was the best way to show its usefulness.

A Scaling Experiment

Heuristic equations pertinent to large-scale models of vertical recording heads and surfaces have been developed in the Appendix. Approximate solutions to these equations have been evaluated and used to find the scaling factors shown in Table I. In every experiment using these equations, a certain degree of interpretation is required. For example, a simple experiment has been performed to illustrate the use and validity of these scaling factors. Two coils of 100 turns each were wound from no. *30* enameled copper wire (diameter of 0.01003 inch) upon coil forms whose dimensions and placements on a magnetic rod are shown in Fig. 1. A second rod and a second set of coils were made with all linear dimensions increased by a factor of 8 ($n=8$). In the second set, no. *12* enameled copper wire (diameter of 0.08081 inch) was used for windings.

An alternating current of varying magnitudes was passed through the primary coil, and the voltage developed in the secondary coil was recorded.

If B_t is the instantaneous field through the secondary coil, the secondary voltage is

Appreciation is expressed to Dr. E. A. Quade, to Dr. A. S. Hoagland, and to C. A. Bergfors for their many helpful suggestions. Through their initial efforts and continued encouragement this study was made possible. The author also acknowledges the helpful co-operation of J. J. Hagopian in furnishing the basic design and the models of the actual vertical recording heads.

Table I. Scaling Factors and Symbols

Parameter	Symbol	Scaling Equation	Comments
Length	l	$l_2=nl_1$	n = scaling factor
Cross-sectional area	A	$A_2=n^2A_1$	
Volume	l^3	$l^3=n^3l^3_1$	
Turns	N	$N_2=N_1$	but use a larger wire to occupy n^3 volume
Inductance	L	$L_2=nL_1$	
Pulse rise time	τ	$\tau_2=n^2\tau_1$	can be adjusted with the amplifier
Writing current	I	$I_2=nI_1$	for $B_2=B_1$
B-field	B	$B_2=B_1$	
Head-to-surface spacing	G	$G_2=nG_1$	
Surface velocity	v	$v_2=\frac{v_1}{n}$	
Surface thickness	T	$T_2=nT_1$	
Signal amplitude	e	$e_2=ne_1$	only for moving and recording heads
Signal width	λ	$\lambda_2=n\lambda_1$	
Thickness of undercoating	W	$W_2=nW_1$	if $W>>T$, this does not need to be adhered to: $\sim 10T$
Wire diameter	d	$d_2=nd_1$	
Permeability	μ	$\mu_1=\mu_2$	
Conductivity	σ	$\sigma_1=\sigma_2$	
Pulse frequency	ω	$\omega_2=\omega_1/n^2$	
Coil resistance	r	$r_2=\frac{r_1}{n}$	if the same material is used, this is already true

$$e_i=N_i\left(\frac{\partial\phi}{\partial_t}\right)=N_iA_i\left(\frac{\partial B_i}{\partial_t}\right)=N_iA_i\omega_iB_{0i}\cos(\omega_i t) \qquad (1)$$

where the subscript $i=1,2$ refers respectively to the small-sized or large-sized model. Consider the maximum secondary voltage as the quantity measured; thus, from equation 1

$$|e_i|=B_{0i}N_iA_i\omega_i \qquad (2)$$

Substitute the properly scaled parameters from Table I into equation 2 to determine the secondary voltage of the large-scale model in terms of the secondary voltage of the small-scale model. Note that the current in the primary coil of the large-scale system must be n times as large as the primary current in the small system.

$$|e_2|=B_{02}N_2A_2\omega_2\doteq B_{01}N_1n^2A_1\frac{\omega_1}{n^2}=B_{01}N_1A_1\omega_1=|e_1| \qquad (3)$$

Fig. 2 is a graph of the secondary voltages versus the primary currents where the primary current of the large scale model has been divided by 8. The coincidence of the curves is a partial check on the validity of the scaling factors.

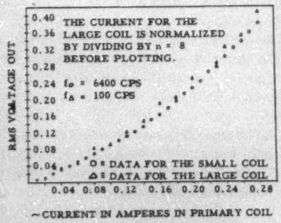

Fig. 2. Scaling experiment

Sensitivity Function

The distribution of the magnetic field around a recording head produced by a current in the windings is defined as the "sensitivity function," $H'(x, y, z)$; and the permanent magnetization left in the recording surface, as $M(x, y, z)$; see Fig. 3. A 2-dimensional plot of the sensitivity function and magnetization for a hypothetical vertical recording head is shown in Fig. 4.

If ϕ is the total flux from the magnetized area of film which threads the coils in the reading head, and v the relative velocity between the reading head and the magnetized surface, the signal voltage developed across the coil may be expressed by the following equation derived by Hoagland:[1]

$$e=K\frac{\partial\phi}{\partial t}=Kv\frac{\partial\left[\int_{-\infty}^{\infty}H'(x)M(x-x_0)dx\right]}{\partial x} \qquad (4)$$

where K is a constant determined by the surface thickness and its saturation distribution. From equation 4 it is apparent that the sensitivity function is used for weighting and represents the degree of coupling between the reading head and the magnetized information on the film.

In first approximation the magnetic recording surfaces used have a rectangular (square-loop) hysteresis loop, and as a consequence the changes in magnetization $[M(x)]$ left in the film are quite narrow when compared with the width of the sensitivity function. According to Hoagland,[1] if the magnetization is assumed to be a step function, i.e., to change from $-M_0$ to $+M_0$ at the point x_0, the voltage developed in the reading head is given by

$$e=2KNvM_0H'(x_0) \qquad (5)$$

where N is the number of turns on the reading coil. This equation states that the signal voltage developed in the reading head has the same shape as the sensitivity function.

Large-Scale Model (Enlarged 40 Times)

It is quite easy to obtain the sensitivity function for a large-scale head using a small pickup loop as a scanning device. If a properly scaled alternating current is passed through the writing coil of a 40×large-scale model head, an alternating H-field will be produced in the vicinity of

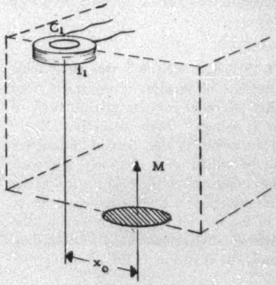

Fig. 3. Reciprocity

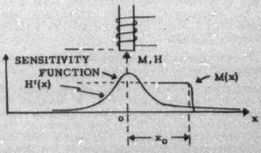

Fig. 4. Weighting

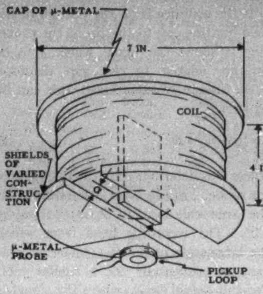

Fig. 5 (left). Simple vertical head

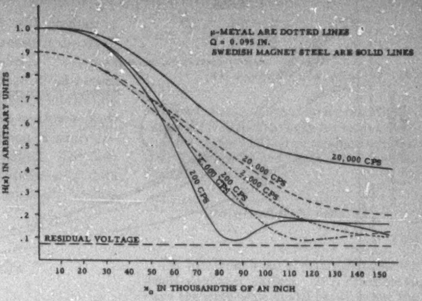

Fig. 6 (right). Sensitivity function versus frequency

the probe. A coil of wire whose diameter is small compared with the probe dimensions placed in this alternating field will have generated in it an electromotive force proportional to the maximum value of the H-field at that point. Thus a plot of these voltages as functions of distances from the probe will be equivalent to a distribution of the H-field around the probe. The orientation of the pickup loop is important since a voltage can be produced only if the component of flux threads it.

In the experimental measurements discussed, only that component of field perpendicular to the recording surface was measured, i.e., the axis of the pickup loop was perpendicular to the recording surface as shown in Fig. 5.

The magnetizing field $H(x)$ which produces the magnetization in the recording surface is much stronger than the reading field and could be much broader than $H'(x)$ because of saturation characteristics of the ferromagnetic metal in the probe of the recording head. In a large-scale model, if $H'(x)$ and $H(x)$ differ widely, then each must be handled by assuming $H'(x)=H(x)$ or by measuring an $H(x)$ for a large-writing current and another $H'(x)$ for an equivalent reading current.

A head enlarged 40 times was constructed as shown in Fig. 5. Because neither the wire size available nor the pulse amplitude were large enough to satisfy the conditions of scaling (i.e., $I_2=nI_1$ and $N_2=N_1$), it was decided to use more turns and a smaller wire size. In spite of this, good plots of the sensitivity function $H'(x)$ and the writing field pattern $H(x)$ were obtained since the rise times and coil resistance were not too critical at the frequencies used.

The pickup loop which was used to plot the distribution of the vertical component of the field from the probe of the large-scale vertical recording head had a diameter approximately one seventh of the width of the probe. A high-impedance vacuum-tube voltmeter was used to measure the voltage. The pickup loop was approximately 100 turns of 0.0025-inch-diameter wire, wound on an 0.012-inch-diameter core. The voltage induced in the pickup loop was in the order of 1 millivolt. Since mumetal is not readily available in thickness large enough to make probes 0.040 inch thick, the shields and probes of the large-scale recording head were laminated from 0.020-inch mumetal stock. To minimize electrostatic voltages being induced in the pickup loop, a common ground was made between the pickup loop and the current source (Hewlett Packard *305A* audio-oscillator). The electrostatic voltage and all other stray voltage not produced by the changing magnetic fields are indicated on the various graphs as "residual voltage."

Fig. 6 is a plot of the e, or $H(x)$ where $H(x)$ is the vertical component of H which changes with the spatial distance x_0, versus the distance x_0 away from the center of the vertical probe. This plot is made for two types of metal and at three different frequencies. Note that the width of $H(x)$ is dependent upon the type of metal

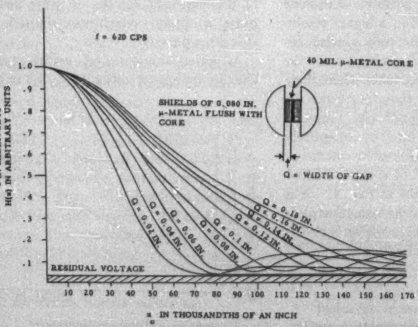

Fig. 7. Sensitivity function versus shield gap for aluminum-backed writing surface

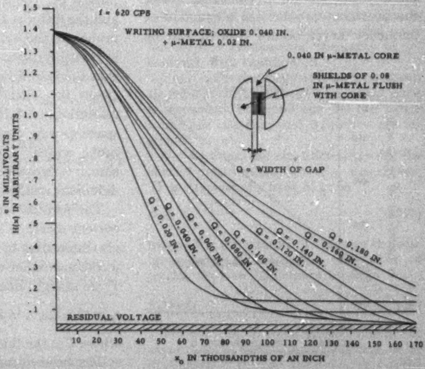

Fig. 8. Sensitivity function versus shield gap for mumetal-backed surface

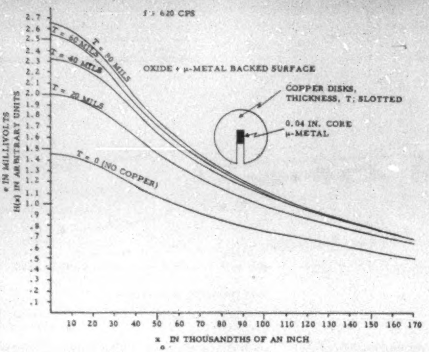

Fig. 9. Sensitivity function versus x, for eddy-current shielding

in the probe and also depends on the frequency. At 200 cycles the edge of the metal of the shields nearest the probe begins to have induced in it an appreciable magnetization of opposite polarity to that of the probe. This would result in an "overshoot" which is a reserval in the direction of magnetization left on the recording surface and causes a corresponding change in polarity of the output voltage induced in the head during reading. In general, this overshoot widens the signal width λ.

Although it is not shown, if the writing current in the large-scale head is reduced, the overshoot disappears for these probes. As illustrated in Fig. 6, the mumetal is not affected by frequency as much as the Swedish magnet steel. It should also be noted that the frequencies for an actual head corresponding to the 200-cps (cycle-per-second), 2,000-cps, and 20,000-cps curves are 320 kc, 3.2 megacycles, and 32 megacycles. For most recording heads, the overshoot problem as a function of frequency never occurs since it can be controlled by reducing the writing current. While the cause of these effects has not been explained, the effects have been found to exist in the small head.

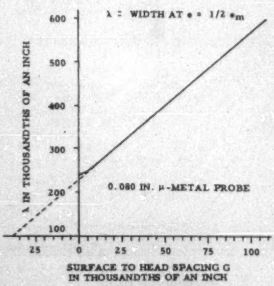

Fig. 10. Resolution as function of head-to-surface spacing

Figs. 7 and 8 show a plot of $H(x)$ versus x_0 with the shield gap Q as a variable. An aluminum-based writing surface is compared with a mumetal-based writing surface in these two figures. The writing surfaces were prepared by coating iron oxide particles (γ-Fe_2O_3) held in an organic binder upon the metal surfaces, and the 0.040-inch coating was deposited upon 0.020-inch metal. It is interesting to note that the width λ of $H(x)$ and $H'(x)$ at the base is linearly related to the width of the gap between the shield and the probe i.e.,

$$\lambda = bQ + C \tag{6}$$

where $b \cong 2$ for a mumetal-based writing surface and $b \cong 1.7$ for an aluminum-based writing surface. The constant C is determined by the thickness of the probe and the distance G, between the tip of the probe and the writing surface. Since one is normally interested in a higher resolution head (and because wide spacing between the shield and probe lowers the resolution) no data were taken where these spacings were greater than four times the probe width. Hoagland[2] has found a similar λ dependence on Q by an entirely different method.

The focusing effect of a slotted eddy-current shield is shown in Fig. 9. It is also interesting to note the logarithm plots of the maximum voltages of Fig. 9 versus T are straight lines indicating that

$$e_m = H(x_0)_{\max} \propto \ln KT \tag{7}$$

where T is the thickness of the shield.

The head-to-surface spacing is an important parameter which was studied with the 40×large-scale model. This spacing G is the distance from the bottom of the field plotting coil to the tip of the probe. Fig. 10 shows the signal width λ to be linearly related to the gap distance. With the use of equation 6, this can be written as

$$\lambda = bQ + mG + D \tag{8}$$

where D is determined by the thickness of the probe. In Fig. 10 m is determined for the large-scale head to be approximately 3.25. The recording head from which the large-scale model was patterned was used experimentally for a similar plot. For this actual head (where the signal is rewritten at each gap) m was found to be 3.3, which is in excellent agreement with the large-scale head.

Large-Scale Model Enlarged Five Times

In the 40×head the sensitivity function, $H'(x)$, and the writing $H(x)$, were found by measuring the voltage induced in a small coil of wire placed in the varying magnetic field around the probe. Because of its large size it was not feasible to use the 40×head to record on a moving surface. For this reason, a 5×head was constructed which was then used to write directly upon a scaled moving surface.

Equation 5 predicts a signal amplitude directly proportional to the velocity of the moving surface. This is experimentally verified in Fig. 11. However, equation 25 predicts the signal from the 5×head to be five times the signal amplitude from the 1×head, if the surface velocities are properly scaled. The signal from the 1× head at 1,500 inches per second is 45 millivolts, and the signal from the 5× head at 300 inches per second is 15 millivolts; this is a ratio of 3 to 1. Neither the surface to head spacing G nor the thickness of the magnetic coating W were scaled quite properly, which contributed to this discrepancy.

As stated previously, the width of the changes in magnetization $\lambda_{M(x)}$, left in the

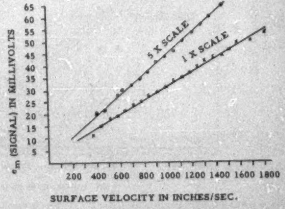

Fig. 11. Surface velocity versus signal voltage

Table II. Large (5X) Dynamic Head Data for Magnetization Width Studies

Units	5× Write* e_s, Millivolts	5× Write* Signal Width, λ, Inches	1× Write† e_s, Millivolts	1× Write† Signal Width, Inches
5× read	42	0.043	2.6	0.036
1× read	8.8	0.022	23	0.0076

* $w=0.0035$ inch; $i_w=0.57$ ampere.
† $w=0.0009$ inch; $i_w=0.2$ ampere.

magnetic surface, should be narrower than the width of the sensitivity function $\lambda_{H'(x)}$. This is expected because in the first approximation the magnetic recording surfaces have square hysteresis loops and the writing field $H(x)$ must reach the effective coercive force of the surface material before the magnetization in the surface changes.

From equation 4 it may be seen that the maximum recovered signal width λ_e cannot be greater than the width of the sensitivity function $\lambda_{H'(x)}$, added to the width of the magnetization $\lambda_{M(x)}$:

$$\lambda_e \leq \lambda_{H'(x)}+\lambda_{M(x)} \tag{9}$$

To obtain some information about the relative contributions of writing and reading to the base width of the recovered signal (signal width on readback), a magnetic bit was recorded with the small head (1×) and read by both the large (5×) and the small head; a bit was recorded also by the large head and read by both the large and the small head. The data are given in Table II.

From Figs. 8 and 9, the $\lambda_{H'(x)}$ for both the 5× and 1× heads can be calculated to be about 0.030 inch and 0.006 inch respectively. Using Table II and equation 9, $\lambda_{M(x)}$ for both the 5× and 1× heads can be determined to be 0.013 inch and 0.0016 inch respectively. The recovered signal width for writing with the 1× head and reading with the 5× head should be given by $\lambda_{M1(x)}+\lambda_{H2(x)}\cong 0.032$ inch, which compares favorably with the measured value of 0.036 inch. Similarly, the recovered signal width for writing with the 5× head and reading with the 1× head should be $\lambda_{M2(x)}+\lambda_{H1(x)}\cong 0.019$ inch, compared to the measured value of 0.022 inch. These qualitative measurements show that for a given recording head used both for writing and reading, the largest portion of the recovered signal width is contributed by reading.

Conclusions

Scaling factors appropriate to magnetic recording heads have been derived in such a way that a linear increase in all lengths in a large-scale model will produce a corresponding linear increase in the space covered by the magnetic field.

The principal advantage of the technique is to relax the precision of fabrication and measuring tolerances so that recording resolution as a function of many parameters may be easily studied. The close agreement between the experimental data from the actual and scaled heads justifies the technique.

Appendix

Theory

In this Appendix some of the equations pertinent to large-scale models of recording heads and systems will be developed. It should be emphasized that, even though the equations and their solutions are not exact, the analogue method used should yield useful information.

D-C Field

The reluctance of a path i in a magnetic recording head is

$$R_i=K\frac{l_i}{\mu_i A_i} \tag{10}$$

where l_i is the length, A_i is the cross-sectional area, and μ_i is the permeability of the path.

Assume a linear increase of n for all dimensions of the path so that $l_{i2}=nl_{i1}$ and $A_{i2}=n^2A_{i1}$; where the second subscript specifies the head being discussed, i.e., the subscript 2 refers to the large-scale head. Thus the ratio of reluctance for corresponding paths in the two heads is

$$R_{i2}=\frac{R_{i1}}{n} \tag{11}$$

provided $\mu_{i2}=\mu_{i1}$

A-C Field

The attenuation of a varying B-field by eddy currents in a semi-infinite slab can be shown[8] to be

$$B_i=B_{0i}\exp\left[-(1+j)\sqrt{\frac{\omega_i\mu_i\sigma_i}{2}}x_i\right] \tag{12}$$

where

B_{0i} = initial B-field at surface
ω_i = frequency of variation of incident B_{0i} field
μ_i = permeability of semi-infinite slab
σ_i = conductivity of semi-infinite slab
x_i = depth of penetration

A heuristic approach is used where the B-field reaching any particular point is used to calculate a pseudoreluctance R_i, i.e.,

$$R_i=\frac{\text{mmf}_i}{\phi_i}=\frac{\text{mmf}_i}{B_iA_i} \tag{13}$$

Thus, with the use of a linear expansion of n times for all dimensions as before, the ratio of reluctance of varying B-fields for any path i becomes

$$R_{i2}=\frac{R_{i1}}{n}\exp\left\{\frac{(1+j)x_{i1}}{\sqrt{2}}\times\left[n\sqrt{\omega_{i2}\mu_{i2}\sigma_{i2}}-\sqrt{\omega_{i1}\mu_{i1}\sigma_{i1}}\right]\right\} \tag{14}$$

where reluctance R is a complex quantity.

Since it is desired to keep the same reluctance for every path (air or conducting material) equations 11 and 14 must be identical. For this to be true

$$\frac{(1+j)x_{i1}}{2}\left[n\sqrt{\omega_{i2}\mu_{i2}\sigma_{i2}}-\sqrt{\omega_{i1}\mu_{i1}\sigma_{i1}}\right]=0 \tag{15}$$

The hysteresis loops of materials make the heads nonlinear devices. It is desirable to have the large-scale model heads follow the same nonlinear response curves as the small head. If the H field at every corresponding point in space and time for both heads is the same, and the identical construction material is used in each head, then $\mu_{i2}=\mu_{i1}$ and $\sigma_{i2}=\sigma_{i1}$, and the heads will have the same nonlinear response. For a linear increase in all dimensions of a current-carrying circuit, it may be shown from Ampere's law that $H_{i1}=H_{i2}$ if one assumes $I_{i2}=nI_{i1}$.

From the preceding assumptions combined with equation 15 the scaling condition imposed upon the frequencies becomes

$$\omega_{i2}=\frac{\omega_{i1}}{n^2} \tag{16}$$

The previous theory applies to the distribution of the magnetic field around the writing probe and in the magnetic recording surface. The distribution of the magnetic field around the writing head is defined as the sensitivity function, $H(x, y, z)$, and the permanent magnetization left in the recording surface as $M(x, y, z)$.

Dynamic Head

In the preceding section only the sensitivity function was considered. To complete the picture the remanent magnetization in a large-scale moving surface must be considered.

First, consider the writing pulse of current; every harmonic of the fundamental frequency in the original pulse must exist in the same proportion in the expanded pulse for the new fundamental frequency in accordance with equation 16.

From a Fourier analysis it may be shown that this condition exists if the current pulse is expanded in amplitude by the factor n and the rise time and frequency are expanded by n^2.

To maintain the condition $H_{i2}=H_{i1}$ the current relationship, $I_{i2}=nI_{i1}$, was chosen. This automatically fixed N_2 to be

$$N_2=N_1 \tag{17}$$

where N is the number of turns on the coil. Since inductance has the dimensions of length, the new inductance becomes

$$L_2=nL_1 \tag{18}$$

For equation 17 to be satisfied and at the same time to allow a linear increase in all dimensions of the coil, the diameter d of the wire should be

$$d_2=nd_1 \tag{19}$$

The time constant of the inductance of the head is a function of the resistance r of the coil as well as the inductance; hence

$$r_2=\frac{r_1}{n} \qquad (20)$$

Since the bits must be spread out on the new large-scale moving surface exactly n times as far apart, the surface velocity becomes

$$v_2=\lambda_2\omega_2=(n\lambda_1)\left(\frac{\omega_1}{n^2}\right)=\frac{\lambda_1\omega_1}{n}=\frac{v_1}{n} \qquad (21)$$

The signal amplitude e is given by

$$e_i=N_i\left(\frac{\partial\phi_i}{\partial_t}\right)=N_i\left(\frac{\partial\phi_i}{\partial x_i}\right)v_i \qquad (22)$$

where N is the number of turns in the recording head and ϕ is given by

$$\phi=SK\int_{-\infty}^{\infty}H(x)M(x)dx \qquad (23)$$

where $H(x)$ is the sensitivity function, $M(x)$ the recording surface remanant magnetization, S the effective cross-sectional area of $M(x)$, and K is a constant determined by the surface characteristics.

Since $S_2=n^2S_1$, $x_2=nx_1$, and $H(x_2)=H(x_1)$, and assuming $M(x_2)=M(x_1)$, it follows that

$$\left(\frac{\partial\phi_2}{\partial x_2}\right)=\frac{n^2S_1}{k}\,\frac{\partial}{\partial x_2}\left\{\int_{-\infty}^{\infty}H(x_1)M(x_1)dx_2\right\}=n^2\left(\frac{\partial\phi_1}{\partial x_1}\right) \qquad (24)$$

and

$$e_2=N_2\left(\frac{\partial\phi_2}{\partial x_2}\right)v_2=N_1\left(n^2\frac{\partial\phi_1}{\partial x_1}\right)\frac{v_1}{n}=ne_1 \qquad (25)$$

A summary of the scaling factors is given in Table I.

Properties of Modern Teleprinters with Regard to Signal Transmission

HERBERT WUSTENEY
NONMEMBER AIEE

Synopsis: The properties of a teleprinter with regard to signal transmission are determined by the performance of three functional units: the drive system, the transmitter, and the receiver. Their design and characteristics in the pageprinter recently developed by Siemens & Halske are subjected to a theoretical examination and practical results discussed. Results coming up very closely to the ideal values have been achieved with simple means.

TODAY the large majority of all teleprinters are installed in the premises of private customers and not in the telegraph offices. These machines are intended for direct record communication between the various offices of the same or of different companies or governmental agencies, and their place is at the side of the office typewriter. In the future, the control of manufacturing processes, the interoperation with computers and with similar equipment for transmission of data will assume, in addition to the present exchange of messages, a very important role.

A modern teleprinter must be tailored to these applications. Therefore it should resemble a conventional office typewriter as regards its outward appearance, it should display elegant styling, and it should be easy to operate. A low operating noise level is highly desirable. Furthermore this machine should work satisfactorily when operated by untrained people and the necessity for servicing by a trained maintenance mechanic should be limited to the bare minimum. Quite a number of companion units are required to meet the various operational requirements and installation as well as removal of these attachments should not present undue difficulties.

If the same machine is supposed to satisfy also the requirement imposed by military organizations for satisfactory operation under severe conditions, operation on board of ships or airplanes for instance, these requirements are likely to have a significant effect on the over-all design of the equipment.

The Teleprinter Is a Telegraph Apparatus

Under all applications the teleprinter is, however, a telegraph apparatus which, to an ever-increasing extent, is required to ensure optimum reliability in message transmission. As a result, great importance must be attached to its properties in this respect. Most of the present teleprinter circuits are made up of a number of line sections with interposed switching centers and carrier systems. Considering the tremendous number of existing teleprinter channels, the use of regenerative repeaters cannot be justified from an economical point of view. Moreover, doubts are already being raised as regards the advisability of employing regenerative repeaters because it is safe to assume that teleprinter channels will some time in the future be used for the transmission of data by means of codes having six, seven, eight and more significant elements which cannot be handled by 5-unit code regenerative repeaters.

Siemens & Halske have recently started production of a new pageprinter model (Fig. 1) which has been designed to meet the afore-mentioned requirements. Properties with regard to signal transmission have been one of the prime considerations.

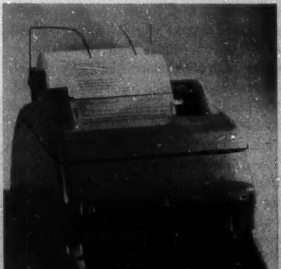

Fig. 1. Siemens pageprinter 100

Paper 59-154, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 15, 1958; made available for printing December 3, 1958.

Herbert Wusteney is with Siemens & Halske AG, Munich, Germany.

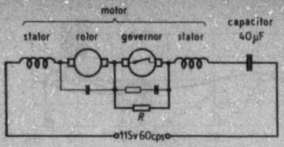

Fig. 2. Circuitry of governed motor

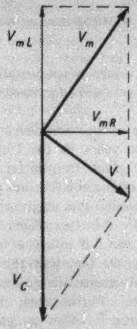

Fig. 3. Voltage values during start-up period at 500 rpm

V = 115 volts, mains voltage

V_m = 162 volts, voltage across motor terminals

V_c = 201 volts, capacitor voltage

The latter are decisively influenced by the following three factors:

Speed of the drive unit with its effect on transmitter and receiver.
Outgoing signal distortion.
Receive margin of selector mechanism.

Motor Speed

COMMUTATOR MOTORS

Many teleprinters are powered by commutator motors with centrifugal contact governors. With a constant load and a constant supply voltage it is easy to achieve a constant speed for a certain period of time. Teleprinters, however, are required to tolerate considerable voltage fluctuations. The load imposed on the drive unit varies during every single operating cycle and, in addition, it depends on the temperature range found under service conditions. An additional requirement is that the start-up time, i.e., the time passing before rated speed and operational readiness are reached, must not exceed one second.

As is known, constant speed in spite of load fluctuations can be attained by increasing the inertia of the rotating masses. To take advantage of this, without excessively prolonging the start-up time, the Siemens pageprinter has a capacitor connected in series with the motor; see Fig. 2. Thus, for instance, a 40-μf (microfarad) capacitor is employed with motors rated for 115 volts, 60 cps (cycles per second). In the rest condition and at low speeds the motor acts as an inductance coil connected in series with the capacitor; see Fig. 3. As a result, the voltage at the motor terminals during the start-up time will be higher than the supply voltage. The effect is a higher start-up torque and reduced start-up time.

The motor has been rated for 3,750 rpm. Its speed has been purposely chosen higher by a certain amount than the synchronous speed of 3,600 rpm at 60 cps and 3,000 rpm at 50 cps, respectively. Governed motors which are operated at the synchronous speed tend to run at the synchronous speed for some time and to suddenly jump by one or by a number of cycles.

Even at an accurate average speed there is still the possibility of brief temporary fluctuations which might have an adverse effect. An electronic measuring method has therefore been employed to determine the actual speed at any given moment. Fig. 4 shows the results of this measurement at a speed of 100 wpm (words per minute).

Fig. 4 (right). Speed curve of governed motor 3,750 min^{-1} 100 wpm 220 volts 50 cps

a = 100 cps
b = line current
c = motor current
d = mechanical load (torque on main shaft)
e = phase position
$\Delta\omega_{max} = -1.35\%$
$\Delta\varphi$ = maximum amplitude of fluctuations during one signal = 0.22 millisecond $\triangleq$ 4.9 degrees $\triangleq$ 1.6% maximum distortion

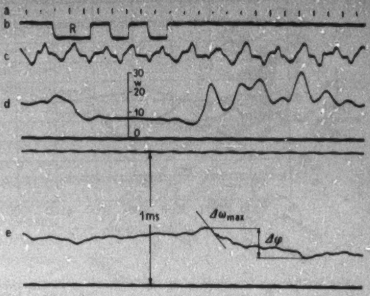

Fig. 5 (right). Influence of voltage on speed

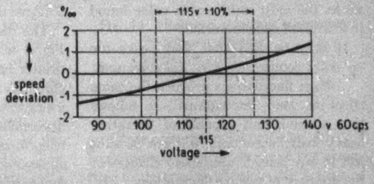

The following characteristics are plotted:

1. 100 cps as the time base.
2. Line current (character *R* transmitted once).
3. Motor current.
4. Mechanical load on drive unit occurring during reception and printing of character *R*. These values have been determined with the aid of strain gages on the main shaft.
5. Phase position of motor shaft with relation to a crystal-controlled standard frequency of 1,000 cps. The bend in this characteristic represents the deviation from the nominal speed. It can be readily seen that the increased mechanical load (curve *d*) results in a momentary decrease in the motor speed. The total phase displacement during the time it takes to transmit one signal is not higher than 0.2 millisecond and this implies an increase in outgoing signal distortion of about 1.6% and a decrease of the receive margin by approximately 1.3%, respectively.

The effect of load fluctuations depends on their phase relation with respect to the operation of the governor (one contact

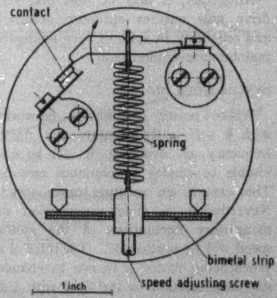

Fig. 6. Governor

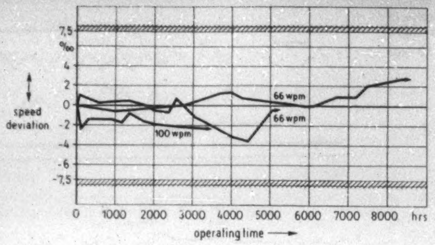

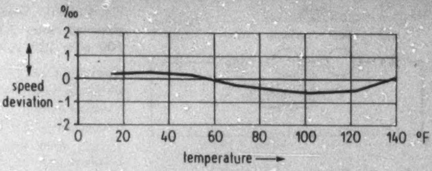

Fig. 7 (left). Influence of operating time on speed

Fig. 8 (above). Influence of temperature on speed

make with each revolution of the motor) and the current wave. The diagram shows the most unfavorable value found in a series of measurements.

It may be said that load peaks are virtually compensated by the drive unit.

Voltage fluctuations produce the same effect as load fluctuations. It follows that a drive unit capable of tolerating heavy load fluctuations will not be subject to any considerable speed changes in the presence of voltage fluctuations. Fig. 5 shows that this assumption holds true over an extended range.

Another factor tending to affect constancy of speed is contact erosion. It decreases the weight of the contact arm and the latter will come closer to the axle (Fig. 6). The governor spring has been designed to compensate this alteration so that readjustment of the speed will not be necessary for an extended period of operation (Fig. 7). The service life of governor contacts by far exceeds 5,000 operating hours.

Since the components of the governor, the steel spring in particular, are rather sensitive to temperature changes, a bimetal strip has been provided as a compensating means (Fig. 8).

The service life of the motor carbon brushes comes up to 3,000 operating hours.

Altogether, it may be said that this drive unit ensures optimum accuracy and reliability in spite of very moderate maintenance requirements.

SYNCHRONOUS MOTORS

Where power distribution networks with a sufficiently accurate and stable frequency are available, it will be advisable to employ synchronous motors. This ensures an accurate mean speed. Nevertheless, a close examination of momentary fluctuations of the motor speed will be worthwhile. The rotor of a synchronous motor is known to change its phase relation to the field with the load. It will lag with a higher load and lead with a smaller load. These changes in the phase position may affect outgoing signal distortion and receive margin to a degree that must not be underestimated.

The diagram in Fig. 9 corresponds to Fig. 4 with the exception that the teleprinter in question is powered by a synchronous motor. Phase displacements as a function of load and torque are clearly discernible and, during the length of one teleprinter signal, produce a shift by approximately 0.29 millisecond, corresponding to 2.2% start-stop distortion.

To avoid a still higher distortion, the synchronous motor had to be designed for a much higher power than was actually required for quick take-up and synchronous operation. In spite of this, the results obtained are less favorable than those obtained with a governed motor.

The pulsating torque is a characteristic of each synchronous motor. It produces gear noise. This can partly be offset by increasing the inertia. Nevertheless, gear noise will always exceed that of a pageprinter with governed motor.

Outgoing Signal Distortion

Distortion caused by speed fluctuations is augmented by the inherent distortion of the transmitter. It has been possible for quite some time already to keep this distortion very low. In particular, transmitters with six contacts, showed excellent results when installed in teleprinters designed for neutral current operation.

For the teleprinters developed during the recent years in the United States a single-contact transmitter has been adopted and the new Siemens pageprinter also has only one single contact. In addition to a further slight increase in accuracy, the advantage of this design consists in the fact that this send contact can be encapsulated to suppress radio interference. Furthermore, it can be easily converted into a polar-current transmitter. Siemens & Halske decided to adopt this design when, by means of a novel and simple arrangement, they succeeded in achieving excellent performance together with an appreciable reduction in the number of adjustments required. Fig. 10 shows the signal generator mechanism.

In the same manner as in the case of other well-known transmitter designs, the bifurcated rocker is shifted either to the right or to the left to prepare transmission either of a marking or of a spacing pulse. Each lobe of the transmitter cam raises the cam follower with its bifurcated rocker and the latter hits against the one or the other extension of the contact rocker bail. Rigidly connected with this bail is the contact plate which is made of insulating material. The control spring of the contact spring set rests

against one of the two lugs of this contact control plate and the contact will be either closed or opened. When the cam follower with the bifurcated rocker is returned to prepare the setting for the next following signal element, the contact must be held in the position determined by the old setting. This is accomplished by a leaf spring forcing the friction brake against the contact control plate. The friction exerted by the spring and the brake holds the contact closed or open, as the case may be. This brake does not require any adjustment nor will it obstruct the movements controlled by the cam and it avoids bounce. Contact bounce proper has been practically eliminated by painstaking calculation and rating of forces, moving masses, and switching speed.

With this design of the transmitter and the measures taken to achieve accurate speed control it became possible to reduce the over-all outgoing signal distortion to less than 3% leading and lagging at a speed of 60 and 66 wpm and to less than 6% at 100 wpm even in the presence of mains voltage fluctuations amounting to ±20%.

A 10,000-hour endurance test carried out in our laboratories revealed that the distortion did not increase by more than 1/2% per 1,000 operating hours.

Receive Margin

The individual operations in a receiver designed for neutral current operation differ considerably from those of a polar-current receiver. Since the large majority of all teleprinters operates on neutral current, the following explanations shall be restricted to this operating option.

In all teleprinters now on the market the receiver has only one magnet and this magnet is called upon to control both the starting of the receiver shaft and the sensing of the five intelligence pulses. A closer study of the problem reveals, however, that these are two rather different functions which have very little in common.

Starting the camshaft of the receiver requires a motion which releases a previously arrested part so that the camshaft is free to revolve. Accurate timing and an excess of power are required. Sensing of the five intelligence pulses is effected merely by testing the position of the armature at certain instants.

To accomplish either of these two functions with optimum accuracy, the new Siemens pageprinter has been provided with a separate armature for each function and these armatures are controlled by a common selector magnet. Each of the two armatures is offered to the magnet by means of a motor-driven cam.

The following is a description of the pulse sampling process; see Fig. 11. The extension of the selector armature rides on the selector cam of the receiver camshaft. For each individual pulse, the selector cam offers the armature to the magnet, i.e., the selector armature is raised so far that only a small gap remains between armature and pole plates. At a closely defined instant, the armature is free to drop unless it will be held by line current flowing through the magnet. A few milliseconds after this release of the armature, the extension of the selector lever moves in the direction of the armature to determine whether the armature is held or released. The extension of the selector lever will continue to move below the armature if the latter is held by the magnet but this movement will be obstructed if the armature is released. Thus, the armature will assume one of two possible positions and, by way of intermediate members, this characteristic setting of the selector lever will be transferred to the code bars of the receiver.

6—Spiral cam disk

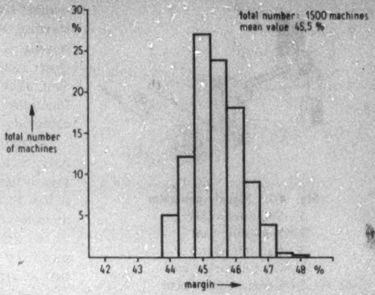

Fig. 14. Teleprinter 100 margin of receiver, 66 wpm

This sampling process takes place approximately in the center of the intelligence pulse. With an ideal receiver it should be possible to shorten each pulse at either side by 50% before a wrong signal is printed or, to express it in other terms, it should be possible to shift a pulse of exactly 100% length in either sense by 50% with regard to the sampling point. To achieve this postulate, certain timing conditions would have to be met which are shown in Fig. 12 for the receiver in question.

Curve *1* represents a current pulse with a contact make time of 100% exactly. The sloped wavefront is due to the self induction of the magnet while the trailing edge is elongated by a spark suppressing capacitor. The magnetic field is shown in curve *2*. The time *c* elapses between the moment the current is switched on and the moment the field has reached its limit value which is required to hold the armature attracted. After switching off the current, the somewhat longer time *b* will elapse before the decaying field has again reached the limit value so that the armature is released. Curve *3* shows the movement of the armature and sampling by the selector lever. At point *A* the armature is raised by the cam lobe, at instant *B* it is being released and allowed to drop unless it is held attracted. At instant *C* the selector lever is just moving into the range of the armature. The distance between *B* and *C* represents the sampling time *a*. Shown at the left-hand side (*A*, *B*, *C*) is one limit position and at the right-hand side (*A'*, *B'*, *C'*) the other limit position of the sampling process.

At the beginning of a current pulse the current may be so far displaced with respect to the sampling instant that instant *B* just coincides with the limit value of the magnetic field. If *B* is ahead of this point, the armature will drop and the selector lever will abut against the front edge of the armature (dashed curve). If *B* is behind this point, the armature remains attracted and the selector lever will not touch it (dash-dot curve).

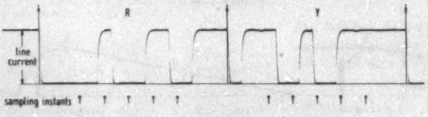
At the end of the current pulse, point *B'* should not be shifted up to the limit value of the magnetic field. The limit position is reached when the magnetic field will hold the armature, after being no more supported by the cam, for a brief moment and will then allow it to drop so far that its tip will just touch the tip of the selector lever (dashed curve). If the magnetic field decays a moment earlier, the armature will hit against the selector lever at *C'*. If the magnetic field will hold the armature a moment longer, the selector lever will pass below the armature.

If the displacement of sampling instant *C* between these two limits is to equal the ideal value of 100%, the following formula will be established with the aid of the diagram

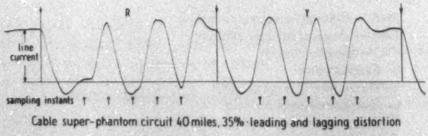
$$a = b - c + f$$

where *f* is the time it takes the armature to drop so far that it will touch the selector lever. The receiver of the Siemens page-printer has been designed to correspond to this formula.

The diagram shows that, during the sampling process, free movement of the armature is limited to only a very small distance so that the possibility of armature bounce is effectively eliminated. The armature is applied to the magnet very slowly and there is plenty of time for it to come to rest. Thus, the sampling process proper is in no way affected by the preceding armature movement or by the shape of the wavefront. It is of prime importance that the essential factors are determined by the design characteristics and are not dependent upon more or less accurate adjustments. Thus, if a disassembled receiver is being reassembled,



Off-line operation, 44% leading and lagging distortion



Cable super-phantom circuit 40 miles, 35% leading and lagging distortion

Fig. 15 (left). Line current in selector magnet of teleprinter 100, 66 wpm

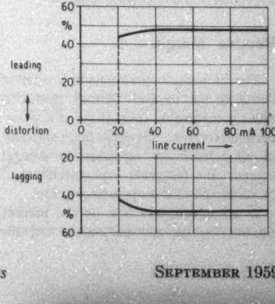


Fig. 16 (right). Teleprinter 100, margin, 66 wpm

Vol. 7
Pt. 1
1959

a wide receive margin will ipso facto be obtained.

A separate armature has been provided for releasing the receiver camshaft; see Fig. 13. In the rest condition, the start-stop armature is held attracted and it will be released by the start pulse. Its extension hits against the crescent-shaped lever and the latter will be pivoted so that locking lever is disengaged. The camshaft will now be turned by way of friction clutch. Since the start-stop armature is required again only at the end of the cycle to stop the shaft, it is raised by the spiral cam disk. It was possible to adopt a very long travel of the start-stop armature. It amounts to 15/32 inches, measured at the tip of the armature. As a result, abundant energy is available for release.

In the rest condition, there is a gap between the extension and the crescent-shaped lever. The armature is therefore allowed to drop freely and it has a considerable momentum when it hits against the crescent-shaped lever. This "striking release" proved to be very reliable.

When the teleprinters are being assembled, the receivers are not adjusted individually for optimum receive margin. Differences of margin resulting from manufacturing tolerances are disregarded. Fig. 14 shows the values measured on 1,500 pageprinters before their shipment to the customer. The mean value of the receive margin was found to be at 45.5% and the minimum value was 44%. These measurements have been carried out with a high-precision electronic distorted signal generator at 66 wpm.

This receiver does not only permit changes in the length of square-wave current pulses but tolerates also extreme distortion values in the case of sloped pulse shapes; see Fig. 15.

Variations of the line current will hardly affect the receive margin (Fig. 16), and it is immaterial whether the machine is operated at, say, 40 or 60 milliamperes.

Conclusions

By selecting a suitable mechanism, by careful rating of components, and by close attention to details in manufacture it is possible to construct with rather simple mechanical means a teleprinter which comes very close to the theoretical limit values as far as outgoing signal distortion and receive margin are concerned.

More About Nonarmored Submarine Cable

C. S. LAWTON
MEMBER AIEE

IN JANUARY 1953 a report[1] was made of the design, manufacture (1950), and laying (October 3, 1951) of an experimental length of novel nonarmored deep-sea submarine telegraph cable[2,3] in 1,250 fathoms of water. In the course of the discussion of the paper it was stated that after a test of about 3 years it was hoped to recover the cable and present a further report on its condition.

Cable Recovery

Actually no suitable opportunity was found to pick it up before the old coastwise section in which it had been installed was taken out of service in January 1955 with the closing of Western Union's Canso, Nova Scotia, station. In July 1955 while the *C. S. Cyrus Field* was in the vicinity an attempt to recover it was made but the ship's dynamometer was insensitive at the low tensions required and the speed of picking up was excessive. The cable parted near the splice to the transitional type on one end, and the bight splice to the armored cable on the other end. No further ship time could be spared until last summer when the *C. S. Lord Kelvin* recovered the entire length laid in 1951 with the exception of 150 fathoms pulled off the ends and recovered in the previous attempt along with the transitional types.

The recovery of this experimental cable on July 26–27, 1958, is of particular significance in the light of recent developments. In 1956 the British Post Office announced "a new deep-sea coaxial cable" the culmination of 5 years of development work,[4,5,6] thus confirming a forecast made in the afore-mentioned discussion that "No obstacle is seen to the design of nonarmored coaxial cable." Not long after came news of the proposal for a single All-British transatlantic telephone cable (to handle 60 simultaneous 2-way telephone conversations) which would be nonarmored throughout the deep-water portion of the route.[7] In July 1958 it was announced that this cable definitely would be a reality by 1961. As a matter of fact, signaling frequencies in carrier-operated transoceanic telephone cables rapidly are approaching the realm where steel-armor wires must be eliminated if attenuation is to be kept within bounds. Whereas laying and recovery tests have been made with nonarmored coaxial cable of British design, there have been no actual service tests to our knowledge.

Both ends having become detached, recovery of the experimental cable with which this report deals had to be effected by grappling for the small cable itself. It was hooked on the second tow 2.04 nautical miles from the east end using 1,750 fathoms of 3 by 3 rope, 6 fathoms of 9/16-inch ground chain, and four 4-hook sets of half-scale Giffords (with a boat grapnel at the tail end for good measure); see Fig. 1. The average towing speed was 0.85 knot, producing an average dynamometer tension reading of 27 cwt (hundredweight = 112 pounds). The cable was hooked about mid-way along the Giffords, the indication being a rise

Fig. 1. Half-scale Gifford grapnel

Paper 59-153, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 31, 1958; made available for printing December 9, 1958.

C. S. LAWTON is with the Western Union Telegraph Company, New York, N. Y.

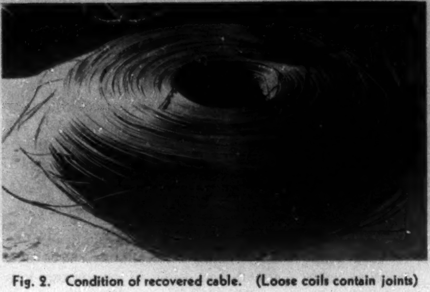

Fig. 2. Condition of recovered cable. (Loose coils contain joints)

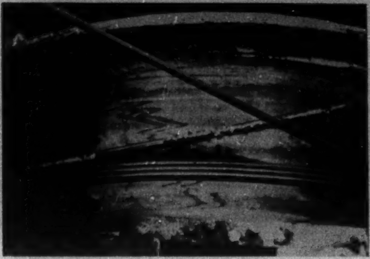

Fig. 3. Parcelling and serving adjacent to joint

of dynamometer tension to 32 cwt. The average speed of raising the grapnel to the surface was 0.31 knot. The tension while doing so dropped from 30 to about 11 cwt. The standing "strain" with both parts of the cable at the bow was 8 cwt.

The short end was found wrapped around the cable for perhaps 50 fathoms when brought to the bow. To be sure of clearing all turns a total of 80 fathoms was picked up on the bight before applying stoppers, cutting off the short end at that point and both parts at the grapnel, thus making it possible to clear the turns and recover the short end separately. This condition was the natural result of the final bight splice dropped at the conclusion of the 1951 laying operation where the nonarmored cable had been spliced directly to the conventional armored cable at the eastern end of the pay-out. (The transitional types had been at the west end.) Upon release of tension, the torsional equilibrium of the armored cable would have been restored by normal twisting, thereby transmitting turns to the adjacent nonarmored cable.

Tension during the actual pick-up which ensued ran between 7 and 9 cwt generally, but with occasional surges to a maximum of about 12 cwt. The picking-up speed averaged about 0.6 knot and while picking up, the downward trend of the cable was aft by 10 to 30 degrees from the vertical. The best condition was found to be about 15 degrees aft, and to our knowledge this is the first time there has been definite substantiation of the theory[8,9] that under certain conditions less tension will be developed if the ship overruns the cable, thereby causing the cable to be inclined forward as it leaves the water. This practice, of course, can be followed only with cable not susceptible to kinking on the bottom when relieved of tension.

Condition of Cable

The main body of the cable came up without any evidence of twisting and coiled down perfectly; see Fig. 2. The polyethylene insulation, which deliberately had been left exposed to worms, if any, showed no evidence of attack except closely adjacent to some of the molded joints where the ship had applied canvas parcelling and untarred hemp spunyarn to elongate the taper in diameter over several feet before laying. These materials as recovered were in poor condition, some frayed or missing entirely, but mostly having to be stripped off for examination of the insulation underneath; see Fig. 3. The evidence was in the form of light scorings, none more than about a thirty-second of an inch in depth but typically at random such as would be caused by teredo attack; see Fig. 4. No worms were found and whether the attack still was in process at the time of recovery is doubtful. It has been suggested that a worm needs support from behind to start the boring action. This would seem to be confirmed. It further has been suggested, in view of the depth of water and proximity of the cable to the Gulf Stream, that these may have been sporadic attacks by stray worms transported by the current and not indigenous to the region at all. Apart from this, the outside of the cable after nearly 7 years submersion could not be distinguished from its condition when manufactured.

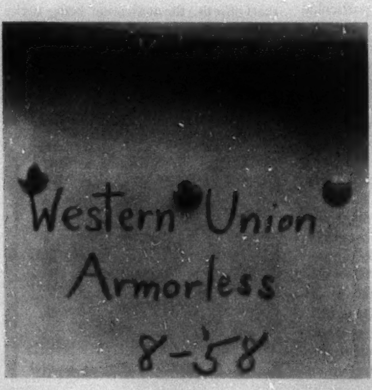

Fig. 4 (left). Nonarmored cable joint—teredo marks accentuated by chalk

Photo courtesy of Bell Telephone Laboratories

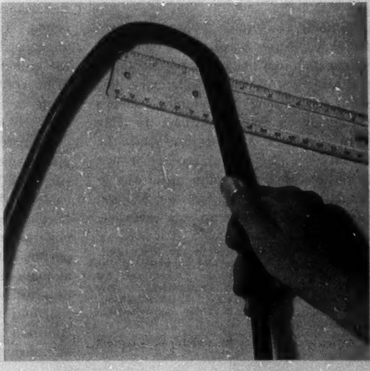

Fig. 5 (right). Cable where hooked and raised by grapnel

One interesting feature of the recovery operation was the bringing of the cable to the surface and inboard over the ship's bow from a depth of over 1,200 fathoms on a Gifford hook, the palm of which was only $2^1/_2$ inches wide, without putting a fault in the cable; see Fig. 5. As a matter of fact, the whole length showed no electrical weakness.

Conclusions

It is evident that a modulus higher than 5 will be necessary for successful recovery in greater depths and that to attain this some use of steel in the strength member is indicated. (When the experimental cable was being designed there was some apprehension about the use of two dissimilar metals since diffusion of water through the dielectric was known to take place and it was thought possible that galvanic action would develop, but this now is recognized as being unlikely because salts do not come through.)

With the successful conclusion of this experiment much of the uncertainty surrounding the ability of nonarmored cable to perform satisfactorily in deep-sea environment has been removed. Naturally, if time was of no importance it would be desirable to make tests in more than one locality and at various depths. Certainly where bad bottom is known to exist with current sufficient to remove the normal deposit of silt, prudence still dictates caution, but it is felt that there now is substantial evidence to support the underlying premise that expensive armor wire on the outside of cable for use in deep water, generally speaking, is unnecessary.

Reperforator-Teletypewriter TT-195( )/FG

D. F. FRICK
NONMEMBER AIEE

Synopsis: Efficient and extremely rapid mechanical energy transfer by means of a design philosophy based on elastic impact of metallic parts made possible the fulfillment of the end function required of a high-speed teletypewriter. Solid-state electronic components enabling data translations and control functions to be performed economically and reliably within minimum space and power limits has proved the final key to practic equipments whose performance far exceeds that of the current standards. The device described in this paper demonstrates the magnitude with which performance might be extended by the marriage of solid-state data-handling techniques with unique mechanical design.

THE ATTACK on the problem of developing a high-speed teletypewriter equipment consisted of extending the electrical signaling and processing of received data as far into the device as practical. The necessity for a mechanical printed and punched paper-tape record obviously requires a mechanical end function, but many decoding and selection operations could be performed electronically, thereby eliminating a large part of the difficulty in achieving high operational speed. A bonus of enhanced reliability, ease of adjustment and maintenance, and greater tolerance to environment and signal distortions were also realized.

The reperforator can be separated into four components providing the following major functions:

1. Selector
   a. Provides signal line isolation from machine ground.
   b. Converts serial 7.0-unit, or longer, Baudot signals, received at one of six discrete transmission rates, into parallel form.
2. Storage Unit
   a. Provides capacity for storing up to 20 5-bit characters.
   b. Address registers and circuitry for insertion of data at constant rates from selector.
   c. Electronic hardware for removal of characters in the order received and delivery upon request by controller.
3. Controller
   a. Converts 5-channel parallel information from storage unit into form acceptable to mechanical unit.
   b. Provides the several electric fundamental outputs to accomplish functions such as ringing signal bell upon reception of sequence FIGS...S, and circuitry to decode shift functions.
4. Mechanical Unit
   a. Together with controller, translates from 5-channel binary information to fundamental (32) outputs.
   b. Punches paper tape with received information.
   c. Provides functions of tape transport, mechanical printing, and upper-lower case shift of typewheel.

The mechanical end function was provided most satisfactorily by utilization of a series of machine elements whose energy and motion were derived by near elastic impact with other machine elements. The usual problems of rebound and vibration were circumvented by using these physical phenomena to advantage within the machine. Figs. 1 and 2 show the reperforator complete and without dust cover respectively.

Controller and Mechanical Unit

A 5-digit binary character is received electrically at the controller. An electromechanical decoding operation is performed resulting in the selection of one of 32 sliding rods. A selected rod presents rigid interference elements in the grooves of a rotating wheel, transferring the selection by means of elastic impact

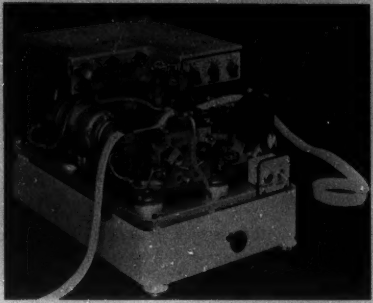

Fig. 2 (right). Reperforator with dust cover removed

to intermediate levers and thence to spring-loaded punches and print hammer. The energy input to the intermediate levers is a function of peripheral wheel velocity, angle of impact between rod and lever, and moment of inertia of the intermediate lever. The latter is adjusted to provide the energy required to perform the desired function, i.e., punch, print, and operate the feed mechanism.

Figs. 3 and 4 illustrate the four locations at which it is possible to select a code rod, each location having eight code rods available, equally spaced about the circumference of a rotating code wheel. These eight shaft positions are monitored by the controller and compared with information from three of the input data bits. The location at which the code rod is to be selected is determined by the states of the remaining two digits of the received data. Each of the four groups of eight rods is displaced 11 degrees 15 minutes of phase from the others. Therefore, the system might be considered equivalent to one wheel containing 32 rods.

The 32-character typewheel is unity geared to the code wheels, resulting in the passage of individual rods past an index point fixed to the machine in registry with each character on the typewheel passing a like index point. A print hammer will be struck by any selected code rod, thereby driving the paper tape into the ink ribbon, into the type face passing the printing position at that time. In addition, each code rod has the five bit code machined into it, interfering with punch operating levers should the rod be selected; see Fig. 5.

The mechanism illustrated in Fig. 6 serves to select the code rods and perform the electromechanical transition at the mechanical unit. When the shaft position monitor has indicated that the desired code rod is about to pass a selection location, an electromagnet removes a latch restraining the "pluck-out" plunger. A leaf spring drives the plunger axially into the path of the passing code rod and the impact resulting from the interference of the ball and cone surfaces of plunger and rod, respectively, drives them apart. The masses of the plunger and code rod are adjusted to provide equal rebound velocities. The impact surface of the plunger consists of a steel ball whose rotation within its socket presents new surfaces to the code rod after each impact; The code rods, likewise, are allowed to rotate freely within the impact wheel. thus, the wear on both ball and cone impact surfaces is distributed over a large area.

The angle of impact of the two elements is a constant independent of the amplitude of interference because of the geometrical shapes of the impact surfaces. The code rod slides axially within the

rotating impact wheel 0.050 inch where it is locked by a detent mechanism. The excess energy of the returning plunger is absorbed by impact with the damping lever shown in Fig. 6. The movement of the damping lever is adjusted so that nearly all of the energy of the plunger is transferred to it causing the plunger to halt, and slowly return to rest upon its latch.

The economy of the system now becomes apparent. The high degree of constancy of the energy imparted to the print hammer results in accurate registration of printing from a typewheel rotating at 3,800 rpm. Further, as mechanical energy is derived from elastic impacts (transfer of selection from code rod to punches and print hammer), the printing and punching operations require a minimum of time enabling operational high speed.

The printing energy is derived from a small mass floating freely in the extreme end of the print hammer; see Fig. 7. When struck by a selected code rod, this print hammer travels upward into a solid stop without contacting the recording medium. An aluminum plunger weighing 0.12 gram is allowed to overtravel the print hammer and drive into the paper tape. In this manner, the contact time of the recording medium with the moving typewheel is kept to a minimum, reducing any tendency to smear.

It should be noted that to search out one discrete position of a rotating shaft may require up to one revolution: 16 milliseconds in this case. As the equipment is required to operate at a rate of 75 operations per second (13.3-millisecond period), the reperforator makes use of the fact that some sequences of characters received might provide several selection possibilities in one revolution.

The mechanical functioning requires a three-eighths revolution to complete eliminating the availability of the first two of the eight shaft positions. Therefore, selections every three-eighths revolution are possible should the received sequence of characters be in correct order. Adverse sequences of characters delivered to the reperforator might require $1^1/_4$ revolutions of search. These rotational displacements are equivalent to slightly less than 6 and 20 milliseconds, respectively, whose average is adequately less than the 13.3-millisecond period between received characters. A mathematical determination of the theoretical frequency distribution of these occurrences with random text indicated that were capacity for storing 20 characters provided, prob-

ability of overflow in such a buffer would be to the order of one in 10^{-6} operations. The reperforator therefore makes use of an internal buffer that delivers characters to the controller upon completion of each preceding selection at the mechanical unit.

Figures-letters shift functions are provided by driving the 2-row typewheel laterally into these positions upon receipt of the shift functions.

Tape transport is accomplished by a ratchet and pawl mechanism shafted to a sprocket engaging feed holes in the paper tape. Torque is applied to the feed ratchet through a torsion-wound straight-wire spring driven by a felt friction clutch. The restraining pawl is removed from the ratchet by impact with an interference element of a selected code rod. The need for accelerating necessarily heavy driven clutch members and shaft is eliminated by the torsion spring coupling. Only the rotational inertia of the lightweight ratchet and feed sprocket need be overcome. The transport of the driving sprocket and paper tape 0.100 inch requires approximately 2 milliseconds.

Storage Unit

The buffer storage unit previously mentioned makes use of 120 binary storage elements. Information is read into the device by comparing the one (Mark) or zero (Space) states of the five input lines with the position of a distributor selecting one of 20 addresses. A sixth bit is stored at each address to facilitate logical removal of characters. The 20 6-bit addresses are available to the 10-position distributors by arranging the character addresses in two decades selected by a single binary stage triggered on each revolution of its associated distributor. The input distributor progresses forward, one address at a time, upon receipt of characters from the reperforator's selector. The output distributor, however, has more stringent requirements to cope with:

1. Characters must be removed in the exact sequence received.
2. It should not be necessary to switch out the storage unit when operating at low speeds or during intermittent signaling.
3. Since the relation between input occurrence and demand for output by the controller is random, care must be taken to insure that characters are not lost or repeated when in-out functions occur simultaneously.

In short, a device is required whose function is that of a "rubber register"—a storage medium that has no capacity when empty, and increases its capacity with filling.

The output distributor is therefore instructed to scan the entire storage unit for the presence of characters while the controller has no data to digest. If a character is inserted in the storage unit, the arrival of the output distributor at that address will cause the controller to act upon that information, ordering the distributor to cease its search. Each time a selection is completed within the controller, the storage unit obeys the order to scan forward. It is then apparent that the output distributor may make many circuits of all addresses between each received character (as at 60 words per

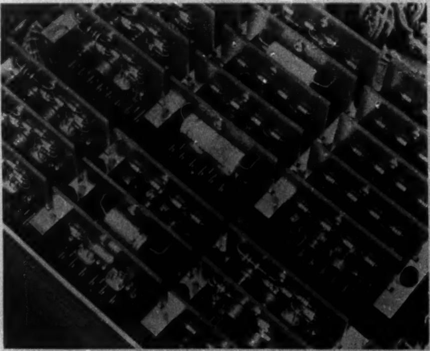

Fig. 10. Modular components of controller

minute), or it may merely "search" forward one address at a time during those periods when several characters remain in storage. Fig. 8 illustrates, in block form, the functioning of the storage unit. Fig. 9 shows the electronic hardware comprising this component.

All logical functioning is accomplished by means of resistor-diode gates and low-level switching transistors. The electromechanical transition at each of the four code rod selection locations is provided by high-speed electromagnets driven by power transistors. A total of 183 germanium transistors and 660 diodes are employed in the reperforator. The unit requires 175 watts of a-c power, weighs 55 pounds, and occupies 1.5 cubic feet of space. The electronic section is constructed of plug-in modular components, each contributing one of several standard logic functions. Fig. 10 shows a group of such modules comprising the controller portion of the reperforator.

Conclusions

The use of elastic impact as a means of energy transfer within a mechanical system has opened the way to practical accomplishment of mechanical functions at very high repetition rates. The equipment previously described has demonstrated specifically that impact printing is not only feasible at high operational speeds, but can be economical and reliable as well.

A Magnetic Amplifier Flow Controller

H. E. DARLING
MEMBER AIEE

Synopsis: An all-magnetic amplifier controller is described. The design has the long life and dependability expected from an all-magnetic circuit and still meets the exacting accuracy and stability requirements of industrial process control. It is intended primarily for fast response (flow) processes, and is designed for 10–50-ma d-c input and output.

AS THE PRESSURE for more efficient production and more uniform products in industrial processes increases, so does the need for more sensitive and reliable instrumentation designs. To meet this demand, industrial instrument manufacturers have been developing electronic control systems, and one such system uses 10–50-ma (milliampere) direct current for intelligence transmission. One component of this system, the controller, has been built which uses magnetic amplifiers exclusively. It will be described with particular emphasis on factors affecting its reliability.

In industrial process control, a large percentage of the controllers are analog computers requiring time functions for integration or differentiation. Since this is normally accomplished by d-c circuitry, the adoption of d-c information transmission made it seem logical to use an all d-c amplifier as a major component in the controller. Magnetic amplifiers which are basically d-c amplifiers, have been developed in recent years to a point where they are the most reliable of all methods of electronic amplification, and within their limits of application, should be ideal for this type of industrial controller design.

The controller to be described is intended primarily for fast response systems such as those encountered in flow control problems. The Foxboro Company has examined the problem of liquid flow in detail[1–4] which led to the development of the well-known *M/59* pneumatic flow controller. Extrapolating from pneumatic experience, a 2-term electronic controller having a proportional band (pb) adjustable from 100–500%, reset times adjustable to 30 seconds per repeat, and no derivative, would be expected to perform in an electronic control system in a manner strictly analogous to the *M/59* in its pneumatic system. From the characteristics of the *M/59* were obtained the original specifications for the all-magnetic amplifier controller.

Factors affecting reliability in the design of magnetic amplifiers for industrial processes has been previously reported,[5] and have been applied throughout the design of this controller.

Specifications

The magnetic amplifier controller is to have the following general characteristics.

1. Proportional band: 100–500%; (10–50-ma input versus 10–50-ma output at 100% pb.)
2. Reset time: variable from 1–30 seconds per repeat.
3. Rate: none.
4. Power supply: 60 cycles, 117 volts, regulated ±2%.
5. Linearity: 0.5%.
6. Zero stability: 0.5%.
7. Adjustable set point: 0–100% scale, accurate ±0.25%.
8. Zero frequency gain: 200 at 100% pb.
9. Frequency response: down 4 db (decibels) at 10 cps (cycles per second).
10. Ripple voltage in output: 1% of full scale voltage.
11. Provided with both manual and automatic operation controls, and arranged for bumpless transfer.
12. Provided with set-point error indicator, and valve position indicator.

Principles of Operation

The block diagram of the controller as used for automatic operation is outlined in Fig. 1. Direct current from a process transmitter is applied to the input terminals of the controller, and the voltage developed at these terminals is opposed by a reference voltage obtained from a precision Zener diode source, the latter serving as a set point. The difference b tween the control and set-point voltage attenuated by the pb adjustment an applied to the input stage of the m amplifier *SSR-1*.

The main amplifier consists of tw caded stages of self-saturating mag amplification *SSR-1* and *SSR-2* w a d-c output, and with the ripple co at of this output reduced by a filter to a low level (0.5%). A portion of the output voltage actuates the process control valve and a portion is applied to an *R-C* time constant network that provides the reset function. Included in the resistance of the time constant network is the resistance of the control winding of a third magnetic amplifier *SSR-3* whose output is returned to the first stage, creating a feedback loop around the main amplifier. A step input applied from the process transmitter is then characterized by the

feedback system to produce a proportional step output followed by reset action.

The main amplifier may also be used to operate the process by manual control, as shown in the block diagram of Fig. 2. The reset circuit and the transmitter input are by-passed through a conventional resistance feedback network, and this feedback voltage is opposed by a second Zener diode reference source, which constitutes a manual positioning adjustment for the unit. In this condition of operation, the amplifier is a stabilized system of 100% pb, and its output valve current follows accurately the settings of the manual set-point voltage.

This method of manual control is only one of several possibilities. For instance, instead of using a common amplifier, the manual and automatic systems could be separate units which would facilitate interchangeability and service of units in the field. Such an approach is under consideration.

Switching means are provided for changing from automatic to manual control and vice versa without upsetting the process, as will be described later.

Description of Amplifier Details

A complete schematic diagram of the controller will be found in Fig. 3, and a description follows.

The input stage of the main amplifier SSR-1 is of the parallel connected self-saturating type, and is provided with two identical control windings to allow electrical isolation between input and feedback circuits. Two additional control windings are required for bias and antihunt purposes.

A center-tapped transformer winding energizes the gate circuits of this stage, requiring the use of only two diodes, thereby reducing to a minimum the number of components used in the gate circuit. Silicon-fused junction diodes are used because of their remarkable electrical and mechanical properties, and their long life expectancy. The load of this gate circuit is the control winding of the second stage.

The 10–50-ma direct current from a process transmitter, when applied to the input terminals of the controller, flows through a 100-ohm precision wire-wound resistor, generating an input voltage be-

tween the limits of 1–5 volts. This input is opposed by a voltage derived from a Zener diode reference source, whose output is manually adjustable by means of a potentiometer from 1–5 volts, and the difference between the two voltages is applied to one of the control windings of the input stage in series with the pb potentiometer. This variable reference voltage is the controller automatic set point, and the difference between the set-point voltage and the process voltage is indicated by a sensitive microammeter when the controller switch is in the automatic operation position. Its purpose is to indicate the deviation of the process from the desired control point.

Bias for this first stage, which must be regulated to a high degree of precision, is derived from a Zener source. The bias current is adjusted to the required value by a series resistor which also acts to prevent the circulation of gate circuit induced voltages in this bias winding. The magnitude of the limiting resistor is many times larger than the ohmic resistance of the bias winding, and because the resistor is of the type that has a small temperature coefficient, the effect of temperature of the bias current is minimized.

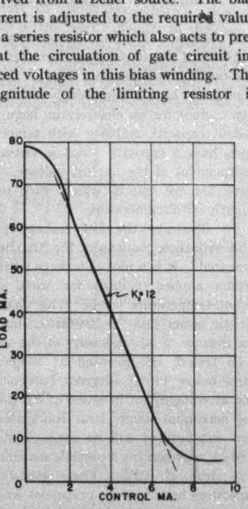

Fig. 5. Stage no. 2 SSR, transfer curve

The transfer curve for this stage (Fig. 4) shows a current gain of 900 in its linear operating region. Further construction details are described in the appendix.

The second stage of the main amplifier SSR-2 is also of the parallel-connected self-saturating type, and is provided with a control, antihunt, and decoupling winding. Maximum reliability again dictates that the gate circuits be supplied from another center-tapped transformer winding, using only two diodes of the silicon-fused junction type.

The output of *SSR-2*, being a chopped-sine waveform, requires a high degree of filtering, and is accomplished by an *L-C*π type filter which reduces the ripple to less than 1%. High-reliability electrolytics were chosen for filter condensers. The output current flows through an indicating ammeter to show valve position, the external load of a valve and other accessories (600 ohms), and then through two precision wire-wound resistors of 100 and 150 ohms respectively. These latter resistors are used for feedback purposes.

With zero control signal into *SSR-1*, its bias is used to adjust the interstage circulating current between it and *SSR-2*, and this current provides the necessary bias for the output stage. By this means, a bias source for *SSR-2* is eliminated, and adds to the reliability of the system.

The transfer curve of *SSR-2* (Fig. 5) shows a current gain of 12. Further construction details are described in the appendix.

With the two stages connected in cascade, the over-all open-loop transfer curve for the amplifier is shown in Fig. 6. An input current change of 3.5 μa (microampere) (3×10^{-9} watts) is required for a 10–50 ma output current change, or the system has an open-loop current gain of 11,000 and a power gain of 87 db. The open-loop frequency response of the main amplifier and its output filter is shown in Fig. 7, indicating that the amplifier and its associated filter has a long time constant.

When used in the automatic control condition, the voltage drop across the 150-ohm resistor in series with the output is applied to an *R-C* time constant network. The purpose of this *R-C* network is to provide the required resetting action of the controller, and also to introduce a fixed amount of derivative for over-all amplifier stabilization.

Specifications of the controller require reset times of 30 seconds per repeat, which is equivalent to saying that the time constant of the reset circuit should be 30 seconds. In vacuum-tube circuitry, the voltage developed across a resistor in series with a reset condenser would be applied to the grid of the tube as a feedback voltage since the vacuum tube constitutes essentially no load upon this resistor, and the feedback circuit then becomes quite simple. In the case of magnetic amplifier, the condition is different because it is difficult to build a magnetic amplifier of sufficiently high input impedance so that serious loading on the reset resistor would not occur. However, it is relatively easy to build a magnetic amplifier that is capable of measur-

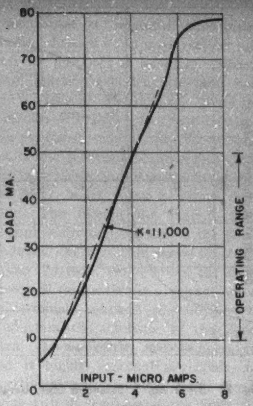

Fig. 6. Main amplifier open-loop transfer curve

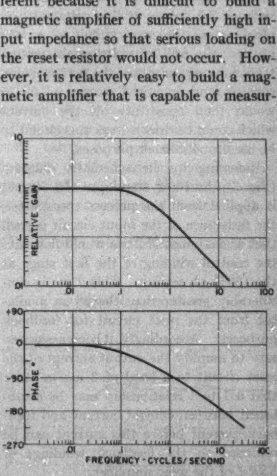

Fig. 7. Main amplifier open-loop frequency response

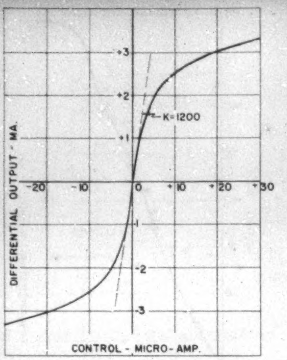

Fig. 8. Stage no. 3 balanced SSR, transfer curve

ing a very small current, and by measuring current flow through the reset resistor rather than the voltage across it, a method is found which is suitable for a magnetic amplifier controller.

In order to get a condenser current flow in the reset circuit of a suitable value, it becomes necessary to use a large capacitor and relatively small resistance in the *R-C* circuit. For the controller being described, a 250-μf (microfarad) capacitor and a reset resistor of 0.27 megohms was chosen. At full-scale output (50 ma), the maximum voltage which would be developed across a 150-ohm feedback resistor is 7.5 volts. If this voltage is applied across the reset circuit as a step change, the full 7.5 volts would instantaneously appear across the 0.27-megohm resistor, and an initial current of 28 μa would then constitute all the current which could be drawn from this circuit to be used for feedback purposes.

Referring to the schematic diagram (Fig. 3), if a 100% step input (10–50 ma) is applied from the process transmitter, the resistance of the input circuit is such that a maximum of 2 ma would flow into the control winding of the first stage at the 100% pb setting. This 2 ma is considerably greater than the 28 μa available from the reset circuit for feedback purposes. Accordingly, it becomes necessary to amplify the output current of the reset circuit to a level of 2 ma in order that a 1 to 1 relationship may be established between control current and feedback current before this current can be returned to the feedback windings of *SSR-1* of the main amplifier.

Adjustment of reset time constant is accomplished by shunting the 0.27-megohm resistor and input winding of *SSR-3* with an adjustable potentiometer. This by-passes a portion of the reset capacitor current and decreases the reset time. This method was chosen because changes in the potentiometer resistance have no effect on the gain of the reset current amplifier, which would change the proportional band of the system. The reset and pb adjustments are virtually independent. At its maximum setting, this potentiometer reduces the maximum current flowing into the control winding of *SSR-3* from 28 to 18 μa.

The amplifier to be used to step up the 18 μa available to the 2-ma level necessary for feedback, must satisfy several stringent requirements. It must be able to sense current of the order of 0.25% of 18 μa, or 0.04 μa (1.1×10^{-12} watts). It must have a zero stability with time and temperature which must not exceed the equivalent input signal change of 0.04 μa, its noise level must be below this same figure, and it must have a stable current gain of 110. It must also be of the balanced type; i.e., for zero input current, the output current must also be zero, and the output must reverse in polarity in accordance with a polarity change of the input signal. If the zero of the amplifier should drift, this would appear to the main amplifier as though the process or the set point had been altered, whereas a change in gain of the amplifier will effect the pb of the system only. Because of the low level at which this reset current amplifier operates, all of the details of its construction become critical.

The special amplifier devised for this application consists of two half-wave self-saturating magnetic amplifiers in push-push combination (Fig. 3). Both gate circuits fire simultaneously on the same half of the 60-cycle signal, and are reset on the opposite half by the bias winding. Each gate circuit supplies current to its own individual load resistance, and the output of the amplifier is taken differentially across these resistors. The amplifier is of the balanced type whose output polarity is directly related to the polarity of the control signal.

The transfer characteristics of this amplifier *SSR-3* working into a load resistor equal to that of one of the 1,000-turn windings of the first stage of the main amplifier, is shown in Fig. 8. The transfer curve is symmetrical with respect to the origin, has a maximum gain of 1,200, and an effective gain at 2 ma output of 400. This amplifier was deliberately made to have a current gain several times larger than that actually required in order that some of this gain could be used degeneratively to linearize and stabilize it. A more detailed description of the construction of this amplifier will be found in the appendix.

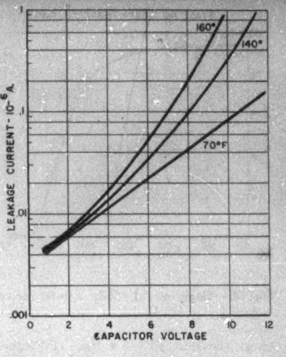

Fig. 9. Leakage current, tantalytic porous plug capacitor

It has been emphasized that this reset current amplifier must have excellent zero stability with time and temperature. It is equally important that the reset condenser used in the time constant circuit has a very small leakage current, because this leakage current when amplified by the reset current amplifier, would be returned to the input of the main amplifier and would appear to that amplifier as though either the control point or process had changed. The reset condenser has a capacity of 250 μf and is an electrolytic of the tantalum porous plug design. These condensers have a surprisingly low leakage current for an electrolytic, have excellent capacity stability with temperature, have a capacity which is virtually independent of the applied voltage, and have leakage effects which vary only slightly with temperature.

To illustrate the low leakage possible with these condensers, Fig. 9 has been prepared. It is a plot of leakage current versus applied voltage for three different temperature levels. This characteristic is not just one condenser, but is the average of 30 condensers of the same type tested. If operated at temperatures below 140 F (degrees Farenheit), and at voltages not in excess of 7.5 volts, the maximum steady state leakage current encountered will be approximately 0.06 μa, representing a possible maximum zero drift of 0.3%. These tantalytic capacitors have leakage properties which approach those of the best paper-foil units available at the present time (having an *R-C* factor of 63,000 megohm-μf), and it is by virtue of this fact that it is possible to make the controller under description. They also have long shelf life, and several years' experience with their use indicates a high degree of reliability. In the controller actually tested, a capacitor was selected from which a maximum zero drift of less than 0.2% is expected.

When the reset loop is closed, the amplifier will hunt due to the time constants of the individual stages used. This is overcome by the use of rate feedback, and is accomplished in two separate paths. The first path is an interconnection between properly polarized windings of *SSR-1* and *SSR-2* of the main amplifier through an isolating resistor (Fig. 3). This method of feedback utilizes circulating second harmonic currents generated by the first stage of the amplifier which flow into the second stage. It is a simple, reliable, and effective way of modifying the time constant of an amplifier without the use of an *R-C* circuit, but can only be used where an even number of self-saturating stages are employed. It also reduces the forward gain of the main amplifier slightly. A small amount of positive feedback around *SSR-2* overcomes the loss of gain. This feedback loop corrects only for the time constant of the two stages of the main amplifier.

A second source of a derivative signal is required for the reset current amplifier, and is obtained by the use of a small amount of resistance-capacity placed ahead of the reset capacitor in the manner customarily used for rate feedback (Fig. 3). Tantalytic capacitors must be used for reasons of stability.[5] With these two feedback circuits properly adjusted, the controller becomes stable under a step upset of any magnitude.

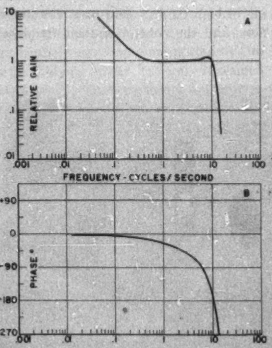

Fig. 10. Frequency response at 100% pb, 1 second repeat

A 3-position switch is provided in the controller in order that bumpless transfer may be made from automatic to manual control or vice versa. In normal automatic operation, the error indicating microammeter is connected differentially between the automatic set-point voltage and the input voltage of the process. When one wishes to transfer to manual control, the switch is placed in its middle position, which leaves the controller on automatic operation but places the error indicator differentially across the manual set-point voltage and the feedback voltage from the 100-ohm resistor in the output circuit. The manual set point is then adjusted until the error indicator reads zero. Under these conditions, the switch can now be turned to its third position, or that of manual control, and since the difference between the feedback voltage and reference voltage is zero, no change in the valve output current will result by this switching operation. The error indicator is at the same time returned to the automatic condition.

Once the switch is placed in the manual position, adjusting the manual set potentiometer will change the valve to any desired position. The amplifier is now a 1 to 1 proportional amplifier with a high degree of degenerative feedback around it and the valve current will faithfully follow the manual set-point adjustment.

When transferring from manual to automatic operation, the automatic set point is adjusted until the error indicator reads zero at which time the switch can be thrown from the manual to the automatic position without disturbing the valve current. By this simple method of switching, bumpless transfer can easily be made from automatic to manual or vice versa.

Reference has been made to the use of Zener systems as a source of constant voltage for both automatic and manual set-point adjustments. These Zener systems use a silicon junction diode having the property that when a voltage is applied across its terminals in the reverse direction, it shows a high resistance until a certain critical voltage is reached, at which point the device rapidly becomes a conductor. Its action is very much like that of a gas regulator tube which is nonconductive until the striking voltage is reached.

These diodes when used in a proper circuit, constitute a precise and reliable source of constant voltage. As shown in Fig. 3, each Zener source obtains its d-c power from a separate transformer winding through a full-wave rectifier and filter for purposes of isolation. Silicon-fused junction rectifiers are used here also for reasons of reliability. Since the controller is designed to operate from a 2% regulated supply, the filtered output of the rectifiers is also regulated to this same value, and in combination with the Zener diodes, forms a 2-stage regulator. The filtered d-c current flows through a limiting resistor to the Zener diode and the fixed load across the Zener diode. At room temperature, the Zener diode will now maintain a voltage across its terminals constant to 0.03%. The conduction characteristic of the Zener diode varies slightly with temperature and is highly reproducible; thus, by inserting a small amount of nickle wire in series with the load across the diode, the temperature effect can be reduced to a very small value. Regulators of this sort have been running for over 3 years with no measurable change in their properties, and have proved to be a precise and reliable source of reference voltage.

Experimental Results

All tests of gain and zero were made using a battery source for input current. Input and output currents were measured with a Rubicon potentiometer as a voltage drop across a precision 10-ohm resistor. In this manner, current could be read in milliamperes directly from the Rubicon scale to four significant figures. A 600-ohm load resistor was used, except as otherwise noted, and the a-c supply to the controller was regulated to ±2%, with an a-c waveform of less than 5% harmonic distortion.

Frequency response measurements were made using a Hewlett-Packard low-frequency oscillator as an input sine-wave source, and both input and output were recorded on a calibrated Brush oscillograph.

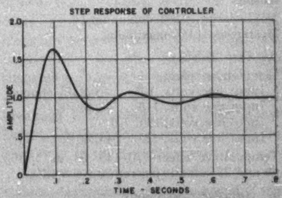

Fig. 11. Step response of controller

Reset time was measured using the

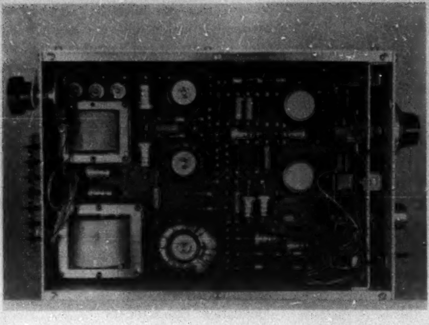

Fig. 12. Research model, magnetic amplifier controller, side view

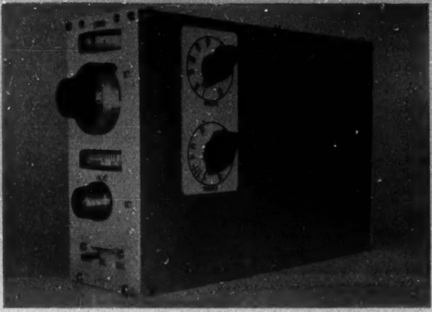

Fig. 13. Research model, magnetic amplifier controller, oblique view

Brush oscillograph. The balance of the controller was upset by a 10% step input from the battery, and the time required for the output to double was read from the chart.

Zero frequency gain was determined by balancing the controller at 0% valve setting using minimum reset time, and measuring the input change required to have the controller rebalance at 100% valve setting.

Ultimate sensitivity was determined at 50% valve setting by observing the smallest change of input that would cause the controller to drift away from the 50% point. This was so small that only an estimate of its value could be made.

Elevated temperature effects were determined by placing the entire controller in an oven at a temperature 70 F above room ambient, and measuring changes in zero, span, and reset times at the elevated temperature.

TEST RESULTS

1. *Proportional Band:* 100–1,000% at 70 F.
Effect of temperature rise (70–140 F) on 100% pb at maximum reset: +0.6%.

2. *Reset Time:* Variable from 1–35 seconds per repeat.

Effect of temperature rise (70–140 F) on reset time at 35 seconds per repeat: 0.

3. *Linearity:* At 100% pb, input versus output.
Nonlinearity, 0.2% maximum
Hysteresis, 0.1% maximum

4. *Zero Stability.*
Line voltage effect.
  Input line volts, 105... −0.25% change
  Input line volts, 115... −0.025%
  Input line volts, 120...0
  Input line volts, 125... +0.05%
Temperature effect (70–140 F) at 100% pb and 35 seconds per repeat: +0.13%.

5. *Adjustable Set Points.*
Effect of temperature (70–140 F) on Zener diode voltage:
  Automatic set, +0.07%
  Manual set, +0.13%
Maximum fluctuation during 24-hour interval at 70 F: 0.03%.

6. *Zero Frequency Gain:* 425 at 100% pb.

7. *Ultimate Sensitivity:* Approximately 0.03% at 100% pb.

8. *Load Sensitivity:* (Change at 100% valve current).
Load, 500 ohms... −0.125%
Load, 600 ohms...0
Load, 900 ohms... +0.15%

9. *Ripple Voltage in Output:* 0.6% peak to peak maximum.

10. *Frequency Response:* (See Fig. 10).
Essentially flat to 6 cps; down 4 db at 10 cps.

11. *Step Response:* At 100% pb and 35 second per repeat; see Fig. 11
Rise time: 0.09 second with 60% overshoot into 600-ohm resistive load
Transport lag: 0.02 second

The controller was tested on the Foxboro liquid flow system[4] using a newly developed electro-hydraulic valve operator and an electronic d/p cell transmitter to form an all-electronic control loop. With a 200% pb and reset of 1.0 second per repeat, operation was found to be virtually identical with that of the analogous *M/59* pneumatic control.

A research model of the controller is shown in Figs. 12 and 13. In these, the general size and type of components used are clearly shown.

Fig. 14 is the production version of the controller package. It is designed for panel mounting, is of the plug-in type, and slides out of its case for adjustment of proportional band and reset. The magnetic amplifier is a plug-in subassembly.

Conclusions

The successful construction of an all-magnetic amplifier controller is the result of the development of a very low power input level magnetic amplifier, the high degree of development of the silicon junction rectifier, and the excellent low leakage properties of tantalum electrolytic capacitors. The successful cascading of high current gain magnetic amplifiers, and the control of their frequency

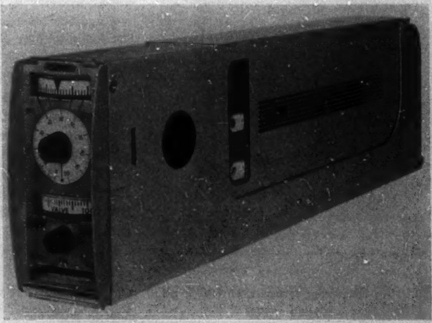

Fig. 14. Production package

response characteristics by feedback techniques makes possible the degree of overall constancy of zero, gain, and time constant required for a precision device. All this has been accomplished without the use of any component of short life expectancy; hence, from the controller described, may be expected a high degree of reliability.

Appendix

The core packages used for both *SSR-1* and *SSR-2* were selected for those properties which yield the ultimate in reliability, and construction details were employed in winding and encapsulating the finished unit with accent on reliability, using the principle reported in reference 5. Winding details are as follows.

SSR-1

Core: 2-mil Hymu *80* tape, matched pair.
  Area = 0.128 cm^2 (centimeter)
  Core length: 6.74 cm
Gate: 1,750 turns no. 34 copper.
Input: 1,000 turns no. 40 copper.
Feedback: 1,000 turns no. 40 copper.
Bias: 500 turns no. 40 copper.
Antihunt: 500 turns no. 40 copper.

SSR-2

Core: 4 mil Orthonol, matched pair.
  Area = 0.544 cm^2
  Core Length: 9.84 cm
Gate: 3,500 turns no. 32 copper.
Input: 250 turns no. 34 copper.
Antihunt: 1,000 turns no. 40 copper.
Decoupling: 12 turns no. 22 copper (short-circuited).

The reason for the use of the short-circuited winding on *SSR-2* has been previously reported.[6,7] These two amplifiers are very similar to those described in these references, although used for a quite different application.

The balanced amplifier *SSR-3* is described in reference 5. Winding details are as follows.

SSR-3

Core: 6 mil Hymu *80* stamped rings, matched pair.
  Area = 0.172 cm^2
  Core length = 5.8 cm
Gate: 1,000 turns no. 34 copper.
Bias: 200 turns no. 34 copper.
Control: 2,500 turns no. 42 copper.

Taut-Band Suspensions for 250-Degree Instruments

V. S. THOMANDER

R. C. MacINDOE
ASSOCIATE MEMBER AIEE

THE taut-band suspension instrument contains a moving element suspended by two metal bands under tension which replace the conventional spiral springs, jewels, and pivot bearings. (The term "taut-band suspension instrument" is used in this paper as reference to an instrument element that is supported by two metal ribbons under tension, sustained by springs.) This new design is free from bearing friction, thus eliminating the major causes of trouble experienced with conventional pivot and jewel bearings such as pivot wear and flattening, or damaged and dirty jewels.

The principal objective that motivated the design and development of the taut-band suspension instrument was the elimination of wear friction between the pivots and jewels. In all conventional switchboard and portable electric indicating instruments employing pivots and jewels, pivot wear and flattening resulting from service and handling has always been a major problem. To keep friction to a minimum: 1. the pivot and jewel cone points have been made with smaller and smaller radii, 2. much has been done to make the pivots of harder and tougher materials, and 3. the surfaces of each are honed and polished to a sheen-like finish. Further improvements have been made by designing moving elements as light in weight as practical. For some instrument designs the jewels have been backed up with a low-pressure spring which permits the jewel to retract under shock, thus allowing a bumper stop to take up the main part of the impact.

Even with the advances in these areas, the remaining friction problem that inevitably exists still places limits on instrument design. In service there still is unavoidable wear which increases friction, with resultant maintenance expense and precautions. Under severe vibration conditions, such as are encountered on railroads and certain types of machines, pivots and jewels have to be replaced periodically.

First Taut-Band Suspension

The obvious solution to the problem of pivot-jewel friction and wear is to try to eliminate it with a frictionless and wearless type of mechanism. An instrument element suspended by strips at high tension was actually used for a short time in Aryton and Perry's D'Arsonval ammeter in 1879.[1,2] It was stated that this type of suspension was "not advisable unless the coil is balanced with exceeding care by the maker, or there is special provision for balancing, for it is difficult to attach the suspension wires so that their axes pass through the center of gravity of the coil when the suspension is drawn taut." There were, of course, other problems and limitations. The elements were too heavy to be supported horizontally by the tautness of the suspension, the suspensions were long, and no provisions were made to prevent breakage from handling or mechanical shock. At best this suspension could be used only in the vertical position.

As the requirement for switchboard instruments expanded into every field of industry, the need for horizontally mounted instruments in many applications became

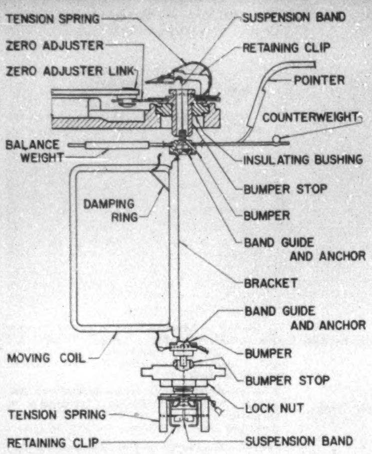

Fig. 1 (left). Taut-band suspension moving element assembly

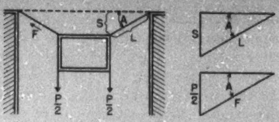

Fig. 2 (right). Sag in a taut-band suspension element in the horizontal position

essential. This may have been a major reason for the concentration on and common use of the pivot-jewel type of mechanisms for instrument moving elements. In any event, pivot-jewel bearings have been standard in instruments for about three-quarters of a century. The continuing research and development on these bearings eventually began to reach the point of diminishing returns, even though the friction problem was not completely solved.

In recent years, European manufacturers[3] have redesigned some of their 90- and 100-degree scale instruments to employ a form of taut-band suspension element. In the United States, the Greibach Instrument Corporation developed a bifilar suspension element. This type of suspension operates on a different principle than the taut-band suspension and therefore will not be discussed in this paper. This paper concerns itself with the taut-band suspension element (Fig. 1) developed by the Westinghouse Instrument Department.

Elements Must Meet Severe Requirements

Recent developments in instrument manufacturing techniques and new materials were major factors in making it possible to develop a taut-band suspension element that would meet the severe standards of performance desired. Other major considerations were that the tension in the band and the element weight be such as to permit the instrument to be used in any position with respect to gravity. The possibility of breaking suspensions under severe shock as well as the side or vertical motion that might introduce rubbing friction had to be overcome.

The over-all size of the taut-band suspension assembly had to be proportioned in comparison to the pivot-jewel-spring assembly, so as to occupy approximately the same space in the instrument mechanism.

Element Sag Equivalent to Pivot-Jewel Side Play

One of the first important design problems was in respect to the amount of element sag. The amount of sag should not exceed the magnitude of side play in a pivot-jewel-type bearing instrument. The smaller this amount the less chance the moving element has of striking any stationary part of the instrument mechanism. Permissible sag had to be limited to allow the instrument to be used in any position with respect to gravity. The band suspensions are taut on either side of the element to the extent that they hold it on rotating center to within three-thousandths of an inch. Mathematically the limits of sag were calculated as follows (Fig. 2):

sine $A = S/L = P/2F$ or

$S = PL/2F$

where

S = the sag

P = element weight

L = length of the taut band

F = tautness or pull on the band

To obtain a small sag both the element weight P and the suspension band length L should be small and the tautness F large. The tautness force should be limited in practice to give a unit tensile stress in the band of approximately 50% of the yield of the band material. The unit tensile stress may vary in extremes from 40–60% of the yield point. This permits use of a given tension spring for slightly different band sizes to match various element torques.

In the new Westinghouse type *KX-241* 250-degree instrument (Fig. 3) the element weight is one gram, the band tautness is 100 grams, and the band length is 0.4 inch. Thus, the sag is $S = 0.4/200 = 0.002$ inch. The total side play is twice the sag or 0.004 inch, or the same order of magnitude as in pivot-jewel type-bearings.

Bumper Stops Solve Problems of Breakage Under Severe Shock and Side or Vertical Motion

The bumper and bumper stops shown in Fig. 1 overcome the possibility of breaking suspensions under severe shock, and relieve overstrains from side or vertical motions of the instrument without introducing any friction.

Zero Set

When the instrument pointer rotates up scale 250 degrees, the twisting end of

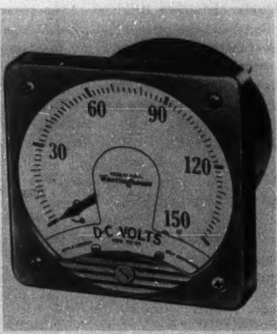

Fig. 3. Permanent magnet moving coil, 250-degree indicating instrument containing the new taut-band suspension element (Westinghouse type KX-241)

each suspension band also turns through 250 degrees with respect to its stationary end. The twisting of the suspension bands in this manner sets up a torsional stress in the band section. If the torsional stress were allowed to exceed the proportional limit of the suspension material, zero set would result. (Zero set is the deflection in degrees that an instrument pointer fails to return to zero when de-energized.) The maximum fiber stress in the cross section of the suspension band, in terms of maximum allowable twist, can be calculated by the following equation:[4]

$$f_s = Gt\theta/L$$

where

f_s = fiber stress, pounds per square inch
G = torsional modulus of the suspension band material, pounds per square inch
t = thickness of the band in inches
θ = twist angle (in the 250-degree instrument it is 4.36 radians)
L = length of the band (in the type *KX-241* element $L = 0.4$ of an inch)

With a given material and length, the maximum band thickness permissible is reached when the fiber stress f_s, in pounds and square inch, reaches the proportional limit of the band material. For no zero set it is then possible to determine a working thickness of a value less than that which will give the fiber stress its proportional limits. It will be noticed that the stress equation does not require consideration of the bandwidth. The bandwidth, therefore, can be selected to give the desired unit tensile strength, element sag, and torque. The fact that the bandwidth is independent of the torsional fiber stress is the reason for using ribbon stock instead of round wire. Not only is the bandwidth selected in terms of the desired tensile strength, sag, and torque, but it also is selected in terms of the desired current capacity and electrical resistance. The width also may be selected for other design reasons. For the *KX-241* instrument, band dimensions have been chosen to give negligible zero set. As tested in the laboratory under 20 to 1 magnification of the pointer and dial, a zero set of only 0.1 degree (0.04% of full scale) was found on the initial 16-hour full-scale deflection. A second full-scale deflection for 48 hours gave no additional zero set that could be detected with this magnification.

A more rigorous test was devised by putting 100 times full-scale current through the element holding the pointer against the full-scale stop. After 12 hours, a zero set of 0.3 degree was found; after 72 hours no further change in zero set was found just as with one milliampere through the element.

Torque Equation

The torque equation developed by Dr. S. Timoshenko[4] is applicable to an instrument element supported at either end by a taut-band suspension. The total torque equation is

$$Tq = 2[(bGWt^3\theta/L) + (TW^2\theta/12L) + (EtW^5\theta^3/360L)]$$

where

b = factor that varies directly with W/t
W = bandwidth, inches
T = band tension, grams, or the unit loading times cross-sectional area of the band
E = Young modulus, pounds per square inch

and other terms are as defined in the previous equations

With narrow bands, the major portion of the torque equation is in the twist component, or the first term of the equation. As the band gets wider the component part, the second term, of the equation becomes proportionally greater. The third term of the equation can be neglected for W/t ratios less than 20. This torque component is due to the elongation of the band edges and the shortening of the band center as the band twists. Where the ratio of bandwidth to thickness ratio exceeds 25, an increasingly nonlinear torque results, producing a nonlinear scale. A good design ratio for W/t is 10 to 1, or for convenience it may vary from 8 to 1 to 15 to 1 and linear torque is maintained.

Torque-to-Weight Ratio Is Not a Factor

The torque-to-weight ratio is frequently used to express the "factor of merit" in pivot-jewel instruments. This ratio indicates the relative ability of the instrument to overcome its bearing friction and give good response action. Of course, it is recognized that torque-to-weight ratio alone does not tell the whole story. The inevitable instrument friction also depends on the pivot and jewel material, dimensions, and workmanship, and on the kind of use the instrument gets. Since the suspension element has no friction surfaces, torque-to-weight ratio is not a factor in determining the friction merits of the instrument.

Torque-to-Inertia Is a Factor

Torque-to-inertia ratio is a more indicative factor of merit for the suspension-type element. That is, to obtain optimum response in an instrument mechanism the suspension element must have a relatively high ratio of torque-to-inertia. Its response time is a function of the damping and the free natural period of the element

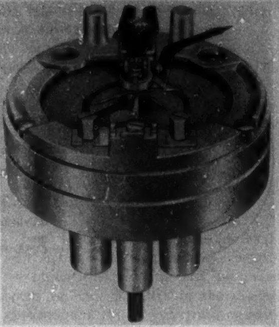

Fig. 4. Instrument mechanism removed from case showing the taut-band suspension element and magnet assembly

$$T_n = 2\pi\sqrt{I/U}$$

where I is the moment of inertia and U the torsional component. The equation shows that the response time varies directly as the square root of its moment of inertia I, and inversely as the square root of the torsional component U. By tests it was determined that good response time is 0.65 to 0.8 of T_n, for a damping factor of 100 to 400. This damping factor spread is for a pointer overshoot of 1 to 0.25% of the scale length respectively. Damping factors of less than 100 give a sudden increase in response time. On the other hand with damping factors greater than 400, the response time increases more slowly. For the optimum response, in accordance with the American Standards,[5] the instrument damping factor should be kept between 100 and 400.

Universal Element

With the type *KX-241* element a one-milliampere full-scale moving-element design is used universally for all ranges of ammeters and voltmeters. The weight of the moving element is one gram. The band suspension is sufficiently strong to permanently maintain a tension of 100 grams. The band is thin enough to twist through 250 degrees without zero set but thick enough to give a response time of $1\frac{1}{4}$ seconds. The resistance of the moving coil and suspension, with the necessary swamping resistance, is well below the limits required for application

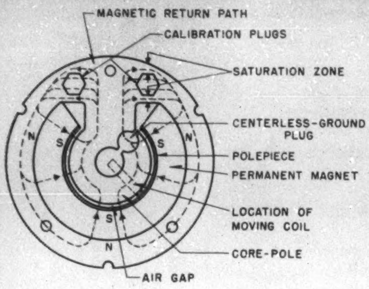

Fig. 5 (left). Magnetic circuit

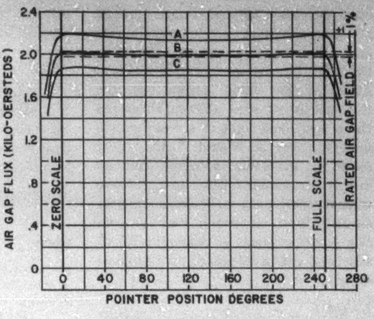

Fig. 6 (right). Curve showing adjustment range of the air-gap field

A—Maximum
B—Nominal
C—Minimum

with 50-millivolt shunts, and with shunt leads up to $1^1/_2$ ohms.

To obtain the optimum weight and inertia in the moving element, all parts are made of aluminum, including the moving coil winding. The moving element is used universally on all voltmeters with full-scale ranges from 50 millivolts to 800 volts, and on all ammeters with full-scale ranges from 1 milliampere to 50 amperes and higher. For lower ranges than these, where the current through the moving coil is the measured value, more turns of smaller diameter wire are used.

SELF-CENTERING TORSION HEAD ASSEMBLY

The complete moving element is self-centering, as shown in Figs. 1 and 4. The casting with the screw thread in the bridge is centered on the magnet circumference for air-gap alignment. The bumper stop screw which mounts in the bridge has a shoulder that locates the tension spring. The form heat-treated beryllium copper tension spring, when compressed to its specified position, centers the suspension band through the bumper stop screw. The other end of the suspension band is centrally attached to the band guide and anchor. The two element bumpers are cemented to the coil bracket with fixtures which align the bumpers with the axes of the suspension bands. The pointer and cross-arm assembly is staked to the top element bumpers. Conventional balance weights are used, and balancing is accomplished in the same manner as on a pivot-jewel-type instrument.

By compressing the tension springs to a specified point, the 0.4-inch suspension band lengths are maintained for accurate torque control. The tension strengths of the springs for each instrument are matched. The dimensions of the suspension band are held to a close tolerance. The band width is held to plus or minus one ten thousandth, and thickness to plus or minus five millionths of an inch. Instrument torque control on the production line therefore is held to extremely close limits.

PERMANENT MAGNET CIRCUIT

The permanent magnet circuit (Fig. 5) consists essentially of a strong Alnico magnet, a pole piece, and a circular lamination stamping of high-permeability high-saturation steel. The permanent magnet is a three-quarter circular ring of rectangular cross-section centerless ground for dimensional accuracy. The stamping is held to close dimensional tolerance and assembles to the magnet with a close fit. The round core section of the lamination extends into the magnet and forms a uniformly circular air gap. The magnetizing is radial which produces a field strength of 2,000 oersteds in the air gap.

One side of the element moving coil rotates in the air gap with ample clearance. The other side of the coil centers through the core opening along the rotating center of the suspension. The coil is assembled through an opening in the ring-shaped core. After the coil is assembled, the opening in the core ring, is closed with a centerless ground steel plug. With this plug in place, a balanced flux path is formed. This path carries the flux from the magnet across the air gap to the core, around to the outer section of the lamination and back to the magnet.

SERIES ADJUSTMENT

The strength of the air-gap field is controlled by a series adjuster in the following manner. In the outer section of the lamination two hexagon holes are placed in a narrow zone of the flux path. The material left in these restricted zones saturates unless similarly shaped plugs are inserted in the hexagon holes. By positioning these plugs the strength of the air-gap field is changed.

This series control is unique in that the air-gap field nearest the adjusted hexagon plug is affected the most. For instance, the scale ends of a zero-center instrument can be equalized and calibrated with these adjusters. On left-zero instruments, the full scale is calibrated by using the left plug and midscale by using the right plug.

To assure a uniform scale between the scale ends and center, a special shape pole piece is attached to the inner face of the magnet. The pole-width taper increases at a predetermined rate from the center to either end of the pole face in a manner to give a uniform scale or pointer deflection. An indication of this linearity is shown in Fig. 6.

Both of the foregoing methods of air-gap field control and adjustments are new features, used for the first time in this new instrument.

ASSEMBLY METHOD

As a subassembly of the instrument the pole piece is attached to the magnet, the magnet to the lamination stack, and all the laminations together by an epoxy resin binder. This means of assembly has been proved adequate for the high-shock requirements. As an example, the total shearing force required to push the magnet from the lamination assembly is 4 tons.

FRICTION

The advantages in eliminating pivot-jewel friction from indicating instruments cannot be overemphasized. The end results are greater sensitivity, increased damping, increased resistance to shock and vibration effect, and reduced maintenance.

Also, by eliminating friction the long-life accuracy rating of an instrument is improved by the amount of the potential friction error that might otherwise accumulate. Although the initial error due

to friction in conventional instruments is small, it will increase with time. On suspension instruments the accuracy rating will remain stable throughout their prolonged service.

LONG LIFE AND LOW MAINTENANCE

With no pivots and bearings to contend with, the life of the instrument is extended beyond any now in use. Under accelerated life tests, the suspension instrument has been subjected to millions of operations without a perceptible change in calibration or change in zero setting. Although these particular test data have been obtained under laboratory conditions, it is sufficient to show that instrument repair and maintenance will be decreased considerably. There is no wear found in the taut-band suspension element even after 8 million zero-to-full-scale operations, and these tests are continuing with no indication that failure will occur. A conventional pivot-jewel-type instrument will require the replacement of the pivots before the first million of such operations.

SHOCK AND VIBRATION

With the conventional instrument the allowable amount of shock or vibration is determined by the durability of the pivot in conjunction with the jewel, and the amount of wear that will occur. The suspension type eliminates these problems. The ruggedness and extended life not only will provide for greater serviceability on present instrument applications, but also will open up new applications for electrical indicating instruments where severe shock and vibration have previously been limiting factors.

LOW ENERGY

Because of the low torque feasible with the suspension instrument, the energy required to operate the instrument is also very low. For example, a conventional 250-degree 1-milliampere instrument requires 0.18 milliwatt for full-scale indication. The suspension instrument, of the same rating, requires only 0.013 milliwatt. In terms of resistance, the conventional instrument of the 1 milliampere range has a resistance of 180 ohms, while the suspension instrument has only 13 ohms.

OVERLOAD

Even though the band is physically very small, and its resistivity comparatively high, it will take severe overloads; for example, at 150 times full-scale overload no damage is done to either the band or the moving coil. At this 15,000% overload the moving coil is required to dissipate less than 0.25 watt which is well within its continuous rating.

For a suddenly applied overload of several thousand per cent the instrument element rotates upscale at a rate directly proportional to the current applied. A current of 150 times full scale will produce a force of 150 times normal full-scale torque. When applying this high overload to a standard production sample of the type *X-241* instrument, allowing element to bump full-scale stops, no error or out of balance can be detected.

VIBRATION AND SHOCK

The Westinghouse type *KX-241* suspension instrument has been tested under the military vibration specification *MIL-Std-167*, simulated shipping tests to meet the requirements of the National Safety Transit Committee, and on various actual shipping conditions from the East Coast to the West Coast by truck, and in all cases the instruments maintained their initial accuracy of 1%. In addition they have been successfully tested under the Navy high-shock specification *MIL-M-16034.*[7]

Conclusions

This taut-band suspension development not only solves many major instrumentation problems of the past, but it also opens up new frontiers in the design, application, and use of electrical measuring instruments for the future.

Performance of the type *KX-241* compared with the requirements of the American Standard *C39.1*,[5] and military specifications[6,7] for 250-degree normal-scale 4$^1/_2$-inch rectangular switchboard d-c electric indicating instruments, see Table I.

Discussion

H. P. Walker (Bureau of Ships, Washington, D. C.): The Bureau of Ships is extremely interested in the taut-band suspension for switchboard meters on the basis of improved operation under conditions of class high-shock and vibration. Consequently, Government laboratory tests were conducted on Westinghouse *KX241* 250-degree scale d-c switchboard milliammeters, to determine compliance with specification *MIL-M-16034A*.

Under exploratory vibration tests per *MIL-STD-167* using a rigid (1/2-inch steel plate) mounting, no zero shift or damage occurred to the meters tested. Total excursion was 2.6% of full scale value at 32 cps (cycles per second) and maximum pointer drift was 6.0% of full-scale value at 31 cps side-to-side motion.

When a 1/8-inch steel-plate mounting was used the two meters tested under side-to-side vibratory motion failed at 31 cps by breaking of the taut bands.

Two additional meters were subjected to class high shock. One meter failed at the 2,000-foot-pound back blow. Failure was caused by the cross-arm pointer assembly becoming disengaged from its supporting tower. Another meter also failed under humidity testing by disengagement of the pointer assembly.

It is urged that additional development work be applied to the taut-band suspension system to provide for a larger safety factor in the band design and a more positive method of securing the pointer.

V. S. Thomander and **R. C. MacIndoe:** The vibration tests performed on these instruments in accordance with *MIL-STD-167* resulted in no damage or change in zero. This agrees with the results reported in the second paragraph of Mr. Walker's discussion. In addition, we found the instruments to be within the limits given in *MIL-M-16034A* which includes changes in calibration due to vibration, and there was no friction effect. The instruments were attached to such rigid mounting brackets that the vibration experienced by the instrument was identical to that of the vibration machine and equal to the values specified in *MIL-STD-167*.

When the instruments are mounted on a less rigid mounting such as the $^1/_8$-inch steel plate referred to by Mr. Walker, the instrument experiences resonant amplification and excitation of other components of vibrations which are unknown but obviously are far in excess of the values in the specification. The specification contains no reference to the exact method of mounting or any mention of the use of a 1/8-inch steel plate. Because of this it is our interpretation of the specification that the values of frequency and amplitude given are the only ones that the instrument is to be subjected to. This was done successfully, as indicated by Mr. Walker's opening comments.

Since the tests referred to in Mr. Walker's discussion were performed, considerable additional improvements have been made in the strength of the joint that failed in both the shock and humidity tests. This was accomplished by changes in the formulation of the epoxy resin used and in the mechanical features of the parts in question. We have tested many instruments employing these improvements, and in all cases, they have successfully withstood both the humidity test and shock test specified in *MIL-M-16034A*.

These tests were performed at Westinghouse locations.

A Wide-Range Volt-Ampere Converter for Current and Voltage Measurements

F. L. HERMACH
MEMBER AIEE

E. S. WILLIAMS
NONMEMBER AIEE

TECHNOLOGICAL developments have brought increasing needs for convenient, portable instruments for measuring current and voltage with high accuracy over a wide range of frequencies. A "universal" volt-ampere (VA) converter has been developed for making such measurements to 0.05% with alternating current at frequencies from 5 cps (cycles per second) to 50 kc and with direct current. The new model is based on an earlier, much more limited prototype converter,[1] and, like it, is used with a null-type d-c potentiometer. With this single, self-contained, portable, 44-range instrument, the 1.5-volt range of a suitable potentiometer can be used to make a-c (rms) and d-c measurements from 7.5 milliamperes (ma) to 20 amperes and from 0.5 volt to 600 volts. With a more sensitive external galvanometer, the instrument can also be used as an a-c–d-c transfer standard for a-c–d-c difference measurements to 0.02% over the same frequency range.

Method

For a-c measurements, a single thermal converter (often called a thermoelement or thermocouple) serves as an a-c–d-c transfer standard. Its heater is connected in series with an a-c resistor for voltage measurements and in parallel with an a-c shunt for current measurements, as shown in Fig. 1. The electromotive force (emf) of the converter is manually balanced by the voltage from a built-in d-c source, with a galvanometer as the indicator (not shown in the figure). The heater of the converter is then switched to a second d-c source, which is adjusted to rebalance the galvanometer. The voltage across a portion of this circuit is then measured with the potentiometer and multiplied by a simple number to obtain the alternating voltage or current. For d-c measurements, the same multiplier is connected as a volt box and the same shunts are used, without the thermal converter.

From Fig. 1(A), with the thermal converter connected to R_m, $V_a=I_a(R_m+R_h)$. With the converter connected to the d-c circuit, the current through the heater is $I_h=I_dR_m'/(R_h+R_m')=V_pR_m'/R_p(R_h+R_m')$. If the a-c–d-c difference of the converter is negligible, $I_a=I_h$, and if $R_m'=R_m$, $V_a=V_pR_m/R_p$. The a-c voltage to be measured is thus the product of the measured potentiometer voltage and a ratio of resistances, and is independent of both the emf-versus-current characteristic and the heater resistance of the converter.

From Fig. 1(B), with the converter connected to R_s, the current through the heater is $I_h=I_aR_s/(R_h+R_s)$. With the converter in the d-c circuit, $V_p=I_d(R_h+R_s')$. If $I_h=I_d$ and $R_s'=R_s$, and if the a-c impedance of the heater is equal to its d-c resistance, $I_a=V_p/R_s$, again desirably independent of the emf-versus-current characteristic and the resistance of the converter.

E_2 = 3 volts, no. 6 dry cells
M = binding posts for external milliammeter

For direct voltage measurements, the heater of the thermal converter is disconnected, the multiplier, R_m, is connected directly to the voltage to be measured, and a 1.5-volt section of it is connected to the potentiometer. If this section is designated as R_a, $V_{dc}=V_pR_m/R_a$, and if $R_a=R_p$ the nominal multiplying factor, $F_e=R_m/R_a$, for the volt box thus formed is the same as that for the corresponding a-c voltage range. For d-c measurements the potential terminals of the shunt R_s are connected directly to the potentiometer, so that $I_{dc}=V_p/R_s$, and again the nominal multiplying factor, $F_i=1/R_s$, is the same as that for the corresponding a-c range.

If the resistors R_p, R_s, R_m, R_m', and R_s' have small proportional corrections of a_p, a_s, a_m, a_m', and a_s' respectively, more detailed analysis shows that, to a sufficient approximation,

$$V_a=\frac{V_pR_m}{R_p}\left[1-a_p+\frac{a_m+a_m'R_h/R_m}{1+R_h/R_m}\right]=V_pF_e(1+v) \quad (1)$$

and

$$I_a=\frac{V_p}{R_s}\left[1-\frac{a_s+a_s'R_s/R_h}{1+R_s/R_h}\right]=V_pF_i\,(1+w) \quad (2)$$

where the capital letters now signify the nominal values. For the useful ranges, $R_m>R_h>R_s$, so that the accuracy required of the compensating resistors R_m' and R_s' is roughly inversely proportional to the current or voltage range, while essentially full accuracy is required of R_m, R_s, and R_p. In practice the over-all correction factors, v and w, are directly

Fig. 3. Volt-ampere converter

evaluated by d-c tests of each range of the instruments.

An instrument which responds to both direct and alternating current is often best tested by evaluating its scale corrections on direct current and then determining its a-c–d-c difference at the desired frequencies[2] (defined as the difference between the direct and alternating current or voltage required to produce the same deflection). This difference is usually small and relatively permanent. Such a-c–d-c difference tests can readily be made with the VA converter by connecting the two instruments together and to a source of the desired voltage or current, making a preliminary setting of the test instrument, and then balancing the emf of the thermal converter, *E*, to give zero deflection of the galvanometer. The instruments are then successively switched to a-c, d-c, reversed d-c, and a-c sources, which are adjusted to give the same deflection of the test instrument, and the resulting galvanometer deflections are observed, without rebalancing. The percentage a-c–d-c difference of the test instrument, *T*, is computed as $T = \Delta D/KE$ where ΔD is the difference between the mean of the two a-c and the two d-c galvanometer deflections, and *K* is a sensitivity factor. This factor is readily determined by observing the changes in galvanometer deflection resulting from small measured differences in applied direct current or voltage at several different levels of heater current, and plotting *K* versus *E*. Tests show that only two such curves are necessary, one of which applies to all current ranges and the other to all voltage ranges. (They differ because of the dependence of heater resistance upon temperature and therefore current.)

Description

A wiring diagram of the VA converter is shown in Fig. 2 and a photograph of the instrument in Fig. 3. The ranges and the nominal shunt and series resistances are listed in the first two columns of Tables I and II, respectively. There are separate input binding posts for the current and voltage circuits, with separate range switches, *A* and *B* in Fig. 2. The instrument can thus be used to measure, in succession, the voltage and current in a d-c or a-c circuit without reconnections. It may also be useful for wattmeter testing on direct current or at unity power factor on alternating current (more strictly at the power factor of maximum deflection of a wattmeter) by the familiar "phantom loading method."[3]

Switch *C* selects the quantity to be measured and switch *D* is the a-c–d-c transfer switch for the thermal converter. The switch markings are identified in the note on Fig. 2. For a d-c measurement, the position of switch *D* is immaterial, and it is only necessary to set the range and selector switches and connect the potentiometer. For an a-c measurement, after these are set switch *D* is rotated to AV No. *1* or AC No. *1*, connecting the thermal converter to the desired a-c source, and the E_1 circuit is adjusted with controls marked "No. *1*" (coarse and fine) for zero deflection of the built-in galvanometer (or any other convenient deflection). Switch *D* is then rotated to AV No. *2* or AC No. *2* connecting the thermal converter to the E_2 circuit which is adjusted with controls marked "No. *2*" to rebalance the galvanometer to the same deflection. The external potentiometer is then read in the usual way. In switch positions marked "Rect. Inst.," (rectifier instrument) two additional poles of switch *D* (not shown in Fig. 2) connect a panel-type rectifier instrument to the a-c input in place of the thermal converter. This is useful for preliminary settings and for checking to make sure that the thermal converter will not be overloaded in the No. *1* position.

A 7.5-ma thermal converter having a heater resistance of $66^2/_3$ ohms is used in the instrument. Because of the compensating resistors, the actual heater resistance need not be closely adjusted. High-quality a-c resistance cards are used for the series and shunt resistors of 1 ohm or more. Shunts of lower resistance, for the higher current ranges, were specially made in our laboratories of bifilar strip, ranging from 2 to 20 mils in thickness, of nickel-chromium-aluminum-iron alloy, with insulation of 1-mil polyester film. The dimensions were chosen as a compromise between the requirements of large area for cooling and of thin strip for

minimum reactance, using inductance and skin-effect formulas developed by Silsbee.[4] The compensating resistors, which carry only small direct current, were chosen to meet the accuracy requirements dictated by equations 1 and 2.

A built-in taut-suspension light-beam galvanometer with 50-millimeter (mm) scale provides a deflection of 2 mm for 0.1% change in input current or voltage at rated heater current. This is adequate for the zero settings required in a-c tests, but for a-c–d-c transfer tests to 0.02%, in which differences in deflection must be read, a more sensitive external box-type galvanometer with a longer scale is connected in place of the internal galvanometer. For these tests an external 1.5-ma d-c milliammeter is also connected at a pair of binding posts marked *M* in Fig. 2, to measure the battery current through the 10-ohm resistor, *e*, and therefore, at balance, the emf, *E*, of the thermocouple.

The VA converter has over-all dimensions of 17x14x9 inches and weighs 30 pounds.

Precautions

A number of factors must be evaluated in the design and construction of an instrument such as this. Some are commonly encountered in the design of any equipment of high accuracy such as a d-c potentiometer, but are accentuated by the high voltage used in some of the circuits. These are: 1. insulation, contact, and lead resistance of the wiring, switches, and other components; 2. self-heating and ambient temperature effects in the shunt and series resistors; and 3. the stability of these resistors. In addition, because of the unusual frequency range in the instrument, the effects of residual reactances, of the a-c resistors, associated circuits, and of the frequency influence of the thermal converter must be carefully considered. Still other factors are peculiar to the use of the thermal converter in this instrument and deserve special mention.

Thermal converters have been studied and used as highly accurate a-c–d-c transfer standards.[5] Normally the average for the two directions of current serves as the d-c reference in transfer measurements. In this instrument, however, only one direction is used for convenience and rapidity of measurement. A converter of small d-c reversal difference is thus desirable. Fortunately, converters of the bead type, with an insulating bead between the heater and thermocouple, can be selected with reversal differences of 0.02% or less. They are then completely interchangeable without requiring recalibration of the instrument.

Most low-range thermal converters have ambient temperature coefficients of 0.1 to 0.2% per degree centigrade (C), and should be thermally protected for precise transfer measurements. A cotton-filled Bakelite cylinder around the converter and the wooden case of the instrument provide a thermal time constant of 40 minutes, which is ample for normal laboratory use of this instrument. A wooden divider separates the shunts and multiplier from the converter and the d-c circuits to minimize self-heating changes.

After a sudden change in heater current, many bead-type thermal converters exhibit an exponential "warm-up" drift having a time constant of 1 to 2 minutes. This drift, an increase of current with time for the same emf, can amount to almost 0.1% for some converters following a change from zero to rated current. The percentage error caused by it is

$$d=\int_{t_1}^{t_2} S\,dt$$

where S is the percentage rate of change of heater current at constant emf and t_2 and t_1 are the elapsed times at which the No. *2* controls and the potentiometer are balanced, respectively. The drift rate did not exceed 0.04% per minute for any 7.5-ma converter tested to date, so that, since 1/2 minute is ordinarily sufficient time for these balances, the warm-up drift error should not exceed 0.02% even for the largest change in heater current. However, for best results, a warm-up period of at least 2 minutes should be allowed. After the initial change, the steady-state drift of the galvanometer in either the No. *1* or No. *2* positions of switch *D* is less than 0.003% per minute, with No. *6* dry cells as the internal d-c sources.

The a-c resistors permit some response of the thermal converter at frequencies up to 100 megacycles (mc). In areas of high television signal strengths, errors can result, since at these frequencies laboratory leads of ordinary lengths can approximate quarter-wave antennas. These difficulties were avoided in this instrument by a low-pass L-C filter with a cutoff frequency of 10 mc per second and a characteristic impedance of 67 ohms, connected to the heater terminals of the thermal converter. The filter changed the a-c–d-c difference of the converter by less than 0.04% [0.003 db (decibels)] at 100 kc.

Tests

The results of d-c tests of the d-c ranges (shunts and voltage divider), and of reversed d-c tests of the a-c ranges of the completed instrument are given in Tables I and II. The results of a-c–d-c difference tests from 20 cps to 50 kc are given in Table III. The d-c shunts were tested with an accurate Kelvin double bridge, and the volt box tested in comparison with the National Bureau of Standards

(NBS) standard volt box. The reversed d-c tests were made with a potentiometer and auxiliary shunts and volt boxes. The a-c–d-c difference tests were made with the NBS standard thermal converters,[5] which have recently been evaluated down to 2 cps, and with a newly constructed transfer voltmeter element, which has been evaluated to 100 kc.

The results of the d-c tests show generally satisfactory performance, adjustment, and stability of the instrument, except for the 10- and 20-ampere ranges in which much larger shunts should have been used. Separate correction curves have been prepared for these ranges to show the change in resistance caused by the self-heating of the measured current.

The a-c–d-c differences, defined as $(I_{ac}-I_{dc})/I_{dc}$ or $(V_{ac}-V_{dc})/V_{dc}$ for the same thermocouple emf with alternating and direct current, are very small. They depend upon the ratios of small reactances to resistances in the instrument and may be expected to remain constant to the accuracy desired. Thus, unless the components are changed, future periodic tests of the instrument need normally be made with direct current only, with a-c–d-c checks made only occasionally. This greatly simplifies the standardization of the instrument.

Additional low-frequency tests of the 0.5-volt and 7.5-ma ranges showed that the a-c–d-c difference of the converter itself is not more than 0.01% at frequencies down to 5 cps. Both theory and experiment indicate that the difference should also be negligible on all other ranges of the instrument.

The small discrepancies in Tables I and II between the corrections for the corresponding d-c and a-c ranges are caused by the d-c reversal difference of the thermal converter, the difference between R_a and R_p, and the influence of the compensating resistors R_m' and R_s'. While these are small (the cause of the relatively large discrepancy [0.06%] between the corrections for the d-c and the a-c 5-ampere ranges is unknown), they are difficult to evaluate separately, so that future d-c tests must probably be made on both a-c and d-c ranges. In most laboratories a volt box and shunt box could be reserved as standards for these and other tests and could be sent to a suitably equipped standardizing laboratory periodically, or the instrument itself could be sent to such a laboratory.

Conclusions

This portable, VA converter can serve as an accessory to a null-type d-c potentiometer to make possible d-c and a-c measurements of very high accuracy over truly wide ranges of voltage, current, and frequency. Its accuracy depends primarily upon wire-wound resistors and strip shunts of excellent stability and low-temperature coefficient. After initial a-c–d-c difference tests of the instrument, routine periodic tests need ordinarily be made only with direct current, thus simplifying the standardization of the instrument.

The VA converter should be particularly suitable for testing other instruments, since all three types of tests, (d-c, a-c, and a-c–d-c transfer tests) may be made with it.

An Impedance Bridge for Surface Temperature Measurement

R. J. MOULY
ASSOCIATE MEMBER AIEE

TEMPERATURE MEASUREMENT and control is a basic requirement in many industrial processes. A common problem is the measurement of surface temperatures without contacting the object because it is inaccessible, moving, or because contacting might damage the surface finish. For example, this is the type of problem encountered when it is desired to control the surface temperature of metal molds or rolls in order to reproduce or maintain temperature conditions which are found to give a satisfactory product. The trend toward higher quality and uniformity of processed products results in increasingly closer temperature limits and correspondingly exacting requirements for the temperature-measuring instrument.

For these applications, the reliability of currently available instruments is often questionable. Some of the limitations of these instruments are listed.

1. Radiation pyrometers are subject to two important sources of error:
   a. The emissivity of highly polished surfaces is often uncertain and varying.
   b. An error results from the absorption of radiation by gases or liquids interposed between the measuring element and the surface whose temperature is to be measured.
2. Aspirating pyrometers are sometimes used, but their application is somewhat limited for moving surfaces such as rolls. They require direct access to the object whose temperature is to be measured and cannot be used whenever adverse ambient conditions exist.

An inductive method of temperature measurement that is free of the foregoing limitations was proposed in the early thirties by G. Keinath.[1] This technique pertains to surface temperature measurements of electrically conductive bodies by means of a special impedance bridge. When an inductive transducer is placed in the vicinity of the surface whose temperature will affect the eddy currents induced in the metal resulting in a change in the impedance of the transducer; this variation unbalances a bridge and is detected by a phase-sensing detector that eliminates the effect of minute distance variations between the transducer and the surface. This measurement method, however, is applicable only to the detection of small temperature deviations as the insensitivity of the output to distance variations is obtained

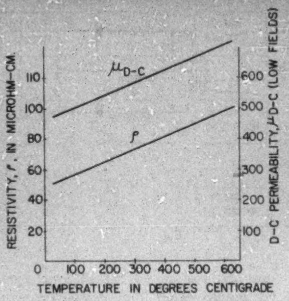

Fig. 1. Resistivity and d-c permeability versus temperature for magnetic stainless-steel type 420

within a relatively narrow temperature range around a preset value.

This paper presents an instrument that permits accurate emissivity-free temperature measurements over a wide range. The method is noncontacting, not even direct (optical) view is required, the speed of response is inherently high, and adverse ambient conditions do not affect the instrument.

TEMPERATURE MEASUREMENT PROBLEM

This instrument has been developed for a specific application: the measurement of the temperature of the glass-contacting surface of molds used in the pressing of glass objects. In some instances, it is desired to control the temperature of the glass-contacting surface very closely, within a few degrees centigrade (C). The measurement problem consists of detecting deviations of the surface temperature of the mold from a reference value.

The emissivity of the mold surface is known to vary with time, therefore, normal temperature measuring techniques may be inaccurate.

Preliminary Considerations

EFFECT OF TEMPERATURE ON THE ELECTRICAL AND MAGNETIC PROPERTIES OF THE METAL

The molds are made of magnetic stainless steel. The surface temperature, when measured, is of the order of 450 to 500 C. At these temperatures, well under the Curie point, the metal still retains its magnetic characteristics and both the permeability and resistivity steadily increase with temperature as shown in Fig. 1. The data on magnetic permeability are only indicative, as the permeability depends upon the flux density.

The metal is in a fully annealed condition and, as its spheroidized microstructure is extremely stable, its electrical properties do not change with time. These properties are therefore functions of temperature only.

EDDY CURRENTS IN MASSIVE CONDUCTIVE BODIES

The temperature measurement technique is based on the generation of eddy currents in the body whose temperature is to be measured. The material is subjected to a sinusoidally varying field and eddy currents are generated that depend on the electrical properties of the metal, resistivity and permeability, and the frequency of alternation of the flux.

If the field is applied parallel to the surface, its amplitude decreases exponentially from the surface to the interior as shown in Fig. 2 for different frequencies.[2] This is true if the thickness of the body is large as compared to the skin thickness which characterizes the penetration of the surface field into the interior and is defined as the distance s from the surface at which the field is $1/\epsilon$ times or 36.8% its surface value.

$$s=5{,}030/\sqrt{\mu f/p}, \text{ centimeters (cm)}$$

ρ = resistivity of material, ohm-cm
μ = permeability of material
f = frequency, cycles per second (cps)

In the particular case under consideration, $\rho=90\ 10^{-1}$ ohm-cm; $\mu=600$ (for low fields), f=200 cps; then $s=0.14$ cm (approximately 1/8 inch). At this frequency, the skin thickness is small compared to the thickness of the mold which is about two inches. Consequently, the eddy currents will be mainly dependent on the electrical and magnetic properties of the metal in the zone immediately beneath the surface of the mold and will be affected by the variations of these properties with temperature.

CHANGE OF INDUCTIVE AND RESISTIVE IMPEDANCES OF AN INDUCTOR PLACED AT A VARYING DISTANCE FROM A SHEET OF MAGNETIC STAINLESS STEEL

An inductor is characterized electrically by the two components of its impedance; its resistance R and its inductive reactance $2\pi fL=\omega L$. If an iron-cored coil, such as represented in Fig. 3, is placed with its axis normal to a thick plate of magnetic stainless steel at a distance d from the surface, its resistance and its inductive reactance will increase. Eddy currents and hyteresis losses will increase

$\omega L_{initial}$=300 ohms

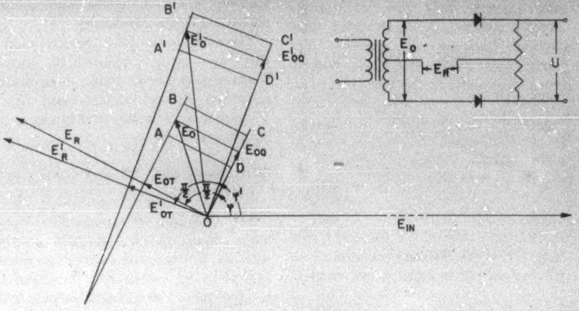

Fig. 7. Phasor diagram for distance modulated probe

the resistance by ΔR and the decrease of the reluctance of the magnetic circuit will result in an increase $\omega \Delta L$ of the inductive reactance. These effects are graphically represented on the impedance diagram in Fig. 4. The plate being at constant temperature T, the impedance phasor will change from OB, inductor alone, to OD corresponding to the inductor impedance when the plate is at a distance d. Distance variations δd around d will result in impedance variations such as DG or DH corresponding to distances $d+\delta d$ or $d-\delta d$

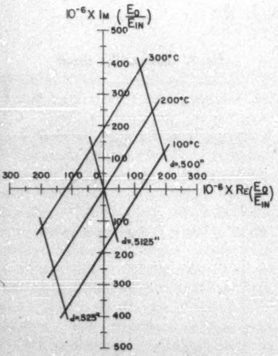

Fig. 6. Bridge unbalance voltage versus impedance variations

See Fig. 5 for f, $R_{initial}$, and $\omega L_{initial}$

EFFECT OF METAL TEMPERATURE CHANGES

If the distance is maintained constant and the temperature of the plate is raised from T to $T+\delta T$, its permeability and resistivity will increase resulting in an inductive reactance increase ($\omega\delta L$), IF in Fig. 4, and a decrease in the iron losses. The latter change appears as a resistance decrease δR, ID in Fig. 4. The impedance of the system will now be OF. Similarly, a plate temperature decrease will result in an impedance change DE. Hence, the direction of an impedance change on the impedance plane is characteristic of the physical origin of the change: distance or temperature.

RELATIVE SENSITIVITIES TO DISTANCE AND TEMPERATURE VARIATIONS—EXPERIMENTAL DATA

The preceding considerations were checked experimentally in order to evaluate quantitatively the order of magnitude of the changes.

Fig. 5 summarizes the results of measurements made at 200 cps on a system consisting of an inductor and a plate of stainless steel in the 100–300 C temperature range and at distances varying from 0.5 to 0.525 inch.

Within that range, the variations of the impedance with distance and temperature around its initial value, corresponding to $d=0.5125$ inch and $T=200$ C are well represented by the linear empirical equations:

$$\delta R = a_{11}\delta d + a_{12}\delta T$$

$$\omega\delta L = a_{21}\delta d + a_{22}\delta T$$

$a_{11} = -5.6$ ohm/inch; $a_{12} = -1.3 \ 10^{-6}$ ohm/C

$a_{21} = -37.2$ ohm/inch; $a_{22} = 1.75 \ 10^{-6}$ ohm/C

The sensitivity to distance variations is such that a distance variation of the order of 10^{-5} inch affects the impedance components as much as a plate temperature change of 1 C.

In an industrial process, minute distance changes of that order are normally unavoidable; it is not even generally possible to define the location of the surface with such accuracies. In order to attain precision in temperature measurement, the output of the instrument will have to be insensitive to minute distance variations between the sensing inductor and the surface whose temperature is being measured.

Instrument Design

MEASUREMENT FREQUENCY

It would seem that the optimum frequency for surface temperature measurement should be as high as possible, as high measurement frequencies are associated with high sensitivities and thin skin thicknesses; however, increasing the measurement frequency results in increased relative sensitivity to surface finish conditions. In the present case, the surface of the stainless-steel molds is plated with a thin layer of chrome whose thickness (maximum 0.0004 inch) and characteristics change with time. It is essential that the temperature indication of the instrument should not be affected by these changing conditions of the surface whose temperature is to be measured. This insensitivity is obtained by lowering the measurement frequency to a value at which the temperature error does not exceed 1 C on the instrument indications.

DESIGN BASIS FOR THE TEMPERATURE MEASURING BRIDGE

The instrumentation problem consists of designing circuitry that will discriminate between the changes of the inductor

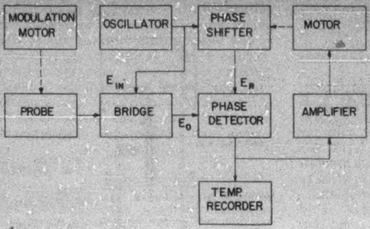

Fig. 8. Circuit for measuring metal plate surface temperature

impedance caused by surface temperature variations and those caused by fluctuations of the probe to surface spacing, and provide an output that is a function of the plate temperature only.

The adopted solution is basically an impedance comparison bridge followed by a phase detector. In an impedance bridge, such as represented in Fig. 3, if the voltages E_{in} across the windings are equal, the real and imaginary parts of the ratio of the unbalance voltage E_o to the input voltage E_{in} are

$$Re\left(\frac{E_o}{E_{in}}\right) \simeq \frac{1}{2}\,\frac{R\delta R+\omega^2 L\delta L}{R^2+L^2\omega^2}$$

$$Im\left(\frac{E_o}{E_{in}}\right) \simeq \frac{1}{2}\,\frac{R\omega\delta L-\omega L\delta R}{R^2+L^2\omega^2}$$

R and ωL being the resistance and the reactance of the probe in the presence of the plate at the initial distance and temperature for which the bridge is balanced. The graph, Fig. 6, shows the variations of the output voltage of the bridge for changes of the plate temperature T and the probe spacing d around their initial values $d=0.5125$ inch and $T=200$ C.

The unbalance voltage components expressed in terms of temperature and distance variations are

$$Re\left(\frac{E_o}{E_{in}}\right) \simeq b_{11}\delta d+b_{12}\delta T$$

$$Im\left(\frac{E_o}{E_{in}}\right) \simeq b_{21}\delta d+b_{22}\delta T$$

with

$$b_{11}=\frac{1}{2}\,\frac{Ra_{11}+L\omega a_{21}}{R^2+L^2\omega^2}$$

$$b_{21}=\frac{1}{2}\,\frac{Ra_{21}-L\omega a_{11}}{R^2+L^2\omega^2}$$

$$b_{12}=\frac{1}{2}\,\frac{Ra_{12}+L\omega a_{22}}{R^2+L^2\omega^2}$$

$$b_{22}=\frac{1}{2}\,\frac{Ra_{22}-L\omega a_{12}}{R^2+L^2\omega^2}$$

The surface temperature and spacing variations result in unbalance voltages of distinct phase.

Any unbalance voltage E_o resulting from simultaneous variations of the temperature and the distance can be resolved into two components E_{oT} and E_{oQ} (Fig. 7). E_{oT} is the component independent of distance and E_{oQ} is the component at right angle to it

$$\frac{E_{OT}}{E_{in}}=\frac{-b_{12}b_{21}+b_{11}b_{22}}{\sqrt{b_{11}^2+b_{21}^2}}\,\delta T$$

$$\frac{E_{OQ}}{E_{in}}=\sqrt{b_{11}^2+b_{21}^2}\,\delta d+\frac{b_{11}b_{12}+b_{21}b_{22}}{\sqrt{b_{11}^2+b_{21}^2}}\,\delta T$$

E_{OT} is temperature dependent only and is the voltage to be measured.

A phase detector, Fig. 7, will detect that component of the error voltage that is in phase with the reference voltage E_R. If the reference is in quadrature with E_{oQ} the d-c output U of the phase detector will be proportional to E_{QT} and depends upon δT only.

Continuous Adjustment of the Phase of the Reference Voltage

The preceding equations show clearly that E_{oQ} is temperature sensitive. Consequently, in order to maintain the quadrature relationship between the phases of the two voltages E_{oQ} and E_R, it is necessary to continuously adjust the phase of the reference voltage when the temperature varies.

Block Diagram

The block diagram, Fig. 8, schematizes how this condition is automatically satisfied in the instrument. The probe is vibrated at low frequency, 20 cps, by the modulation motor, in order sinusoidally to modulate the spacing between the inductor and the plate. The error voltage E_o, Fig. 7, oscillates between OA and OB and is amplitude and phase modulated. The phase of the reference voltage E_R is adjustable by the phase shifter whose position is controlled by a servo system.

As long as the reference voltage is not in quadrature with E_{oQ}, a 20-cps signal is present in the output of the phase detector. This a-c component is the error signal input of the servo system that adjusts the resolver position until the 20-cps component disappears from the output of the phase detector, at which time the reference voltage is in quadrature with E_{oQ} and the output of the phase detector is a function of δT only.

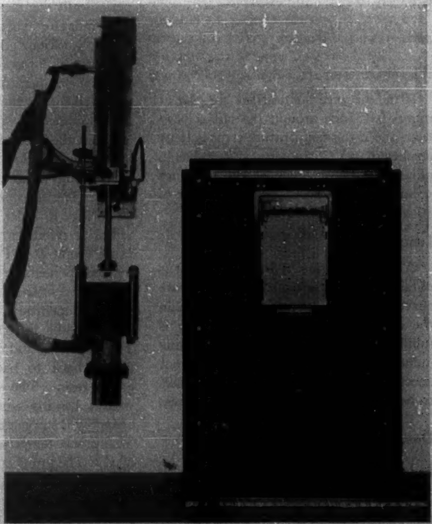

Fig. 9. Surface temperature measuring system showing inductive probe, left, power supply and bridge unit, right

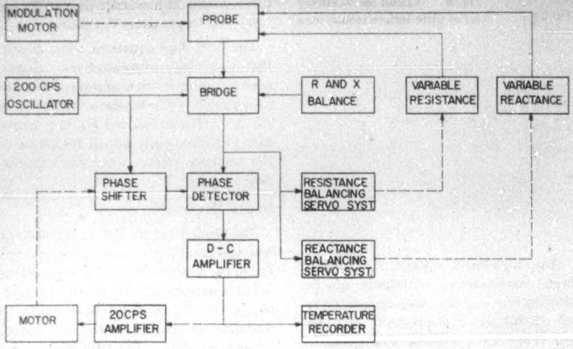

Fig. 10. Block diagram of temperature measuring instrument

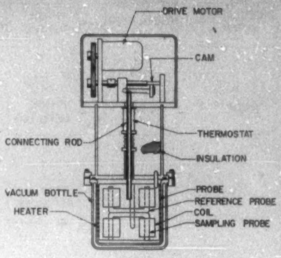

Fig. 11. Inductive probe details

Typical Values

Relative Amplitudes of E_{oT} and E_{oQ}. In the instrument

$d \cong 0.5$ inch
$100 \text{ C} < T < 500 \text{ C}$

in presence of molds of stainless-steel type *420*

R initial = 700 ohms
ωL initial = 300 ohms
$E_{in} = 5$ volts
$E_{oT}/\delta T = 6 \ 10^{-6}$ volt per degree centigrade
$E_{oQ}/\delta d = 2 \ 10^{-3}$ volt per 0.01 inch

Effect of Nonquadrature of E_R and E_{oQ} If the phase difference is $\pi/2 - \epsilon$ instead of $\pi/2$, an error voltage of the order of ϵE_{oQ} is added to E_{oT}. For example:

$$\delta d = 0.01 \text{ inch}; \ \frac{E_{oQ}}{E_{oT}} = 333$$

if $\epsilon = 10$ minutes; $\epsilon E_{oQ} \cong 1$ C

If the distance fluctuations are plus or minus 0.01 inch around the initial position, and if the temperature error is to be smaller than 1 C, the servo system has to adjust the phase angle of the reference voltage with an accuracy of the order of 10 minutes.

Discussion

Correct operation of the instrument is obtained only if the constant temperature curves in Fig. 5 are straight lines within the operating range. This condition is fulfilled by proper design of the sensing inductor. It will be noted that it is not necessary for the constant distance lines to be straight within the operating zone.

Description of Instrument

Equipment Details

The industrial version of the instrument is shown in Fig. 9. The equipment is specially adapted for mold temperature surface measurements for temperatures up to 500 C. The probe can be lowered into the measuring position, in the vicinity of the surface, by means of an air cylinder. When in the upper position, the impedance of the probe is not affected by the presence of the molds.

The block diagram, Fig. 10, schematizes the over-all configuration of the circuit which is derived from the basic block diagram, Fig. 8.

The following features have been incorporated to obtain a high degree of stability in the instrument readings. The impedance of the sensing inductor is periodically compared to that of the reference inductor whenever the probe is in the up position. Any impedance difference caused, for example, by aging or to a variable temperature gradient, is compensated for by the resistance and reactance components.

When the probe is in the temperature measuring position, additional balancing components (R and X balance as shown in Fig. 10) are inserted in the arms of the bridge in order to balance it for the initial or reference temperature and distance (point D in Figs. 4 and 5). These two components are adjusted once in a given process and are mounted in a constant temperature oven.

The probe is represented in Fig. 11. The reference and sensing inductors are placed back to back, embedded in an epoxy resin. The embedment is wound with a heating winding and the entire assembly is suspended in a vacuum bottle. The probe temperature is stabilized at 50 C. The probe is vibrated axially with a maximum amplitude of the order of 0.001 inch by a constant-speed cam and a motor mounted in the upper part.

Instrument Performances

The instrument can operate continuously and detect surface temperature variations of the order of 1 C at temperatures up to 500 C. The over-all time of response is about 5 seconds; although, when balanced, a 5 C per second rate of change of mold surface temperature can be followed. The output is insensitive to spacing variations of 0.01 inch. The readings are emissivity free and the measurements are performed without contacting the mold surface.

Other Applications

The measurement technique is applicable to temperature measurement of conductive nonmagnetic bodies. In this case, if surface temperature measurements were desired, it would be necessary to operate at higher measurement frequencies. The method is equally applicable to electrodeless conductivity measurements.

Discussion

Donald L. Waidelich (University of Missouri, Columbia, Mo.): The method of measuring temperature by the use of an eddy-current probe coil described in this paper by Mr. Mouly is very interesting. The application of a phase detector to minimize the effect of the variation of the spacing of the probe from the metal surface is very similar to the method employed earlier by Dr. F. Förster.[1] In modulating the spacing of the probe from the metal, Mr. Mouly has introduced a useful way of providing a voltage so that the phase relationships can be adjusted readily. Another method[2] of neutralizing the distance component of the voltage utilizes a compensating circuit with the output obtained from an electronic phase meter.

R. J. Mouly: The application of a phase detector to minimize the effect of the variation of the spacing of the probe from the metal surface was employed by G. Keinath and was mentioned in the literature as early as 1934.[1]

Simple-phase detectors of the type used by G. Keinath or F. Förster, however, do not offer a satisfactory solution to the temperature measurement problem described in the paper. They provide an output insensitive to distance variation within a narrow temperature range; theoretically the insensitivity would be achieved for one temperature only. The continuous, automatic adjustment of the phase of the reference voltage becomes a necessity if measurements are to be made over a wide temperature range. This is the essential feature of the instrument.

Naturally, these considerations are applicable to the inductive measurement of electric or magnetic properties whenever it is desired to perform reproducible measurements within a wide range of values.

The Inductronic Electrodynamometer for the Precise Measurement of Voltage, Current, Power, and Energy

R. F. ESTOPPEY
MEMBER AIEE

THE Inductronic* electrodynamometer has been perfected and retested in its final form, and complete information concerning its design and performance can be given at this time. An interim report[1] has been presented covering much of this material, and this paper includes the prior material as well as additional new information. A complete wiring diagram is now included along with output response-time curves and a means of controlling the damping by an external network. Shielding from the effects of external magnetic fields has been improved along with more precise frequency compensation. The network used to obtain this compensation is included.

General Description

The Inductronic electrodynamometer was developed for use as a product resolver[2] for the multiplication of two electric inputs to produce an output current accurately related to the product of the two input currents. The capabilities of this unit have now been extended to include the measurement of voltage, current, and power at 0.1% rated accuracy on direct and alternating currents to 2,500 cps (cycles per second). Transfer error between direct and alternating current is less than 0.04% with readability and resolution of better than 0.02%. Response is fast and power loss is less than that of a conventional dynamometer.

These features have been accomplished by combining an electrodynamometer and a permanent-magnet moving-coil mechanism with the Inductronic amplifier.[3,4] The combining of the two mechanisms is similar to the Shotter-Hawks Comparator,[5] but the addition of the amplifier provides direct current which automatically provides a balancing torque, whereas the comparator requires the introduction of a known direct current for balance.

The product resolver consists of a dynamometer mechanism and a permanent-magnet mechanism having their moving coils mounted on a common staff. The torque of the dynamometer element is automatically balanced by a current fed back into the d-c moving coil from a d-c amplifier, arranged to provide a full feedback current. This amplifier supplies the current needed to produce the counter torque which keeps the system in balance.

Referring to the block diagram in Fig. 1, the dynamometer element is shown at the top with the d-c or torque balance induction element directly below.

The d-c mechanism is supplied with powdered iron inserts set into solid iron pole pieces and core. The magnet produces a steady flux linking the moving coil by means of the solid iron structure, and a 200-kc field is produced in the powdered iron inserts by means of the induction field coils which are attached to the magnet structure. The excitation for the induction field is supplied by an oscillator included within the amplifier, which also amplifies any a-c signal, about 200 kc, induced in the moving coil. With no current in the dynamometer coils, the moving element is kept in a position where the d-c moving coil does not link the 200-kc flux. As current is applied to the dynamometer coils, a torque is produced causing the moving element to turn. The d-c moving coil then links the 200-kc flux and produces a signal which is amplified, rectified, measured, and fed back as a

Paper 59-165, recommended by the AIEE Indicating and Integrating Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted November 5, 1958; made available for printing December 23, 1958.

R. F. ESTOPPEY is with Weston Instruments, Division of Daystrom Inc., Newark, N. J.

direct current to produce a torque exactly equal to the dynamometer element torque.

The torque produced by the dynamometer element is directly proportional to the in-phase product of the input currents to the dynamometer coils. An equal counter torque is developed which is proportional to the d-c output current. Therefore, the in-phase product of the input currents is proportional to the output direct current. This direct current varies from 0–1 ma (milliampere) and can be measured by a d-c indicating instrument, precision potentiometer, digital voltmeter, recorder, etc. It can also be used for control purposes.

Damping is supplied by a derivative damping amplifier since the damping of the d-c mechanism is insufficient because of the relatively high moment of inertia of the moving element and high electric torque applied to the moving system. The amplifier responds to the output current change and feeds back a rate-of-change counter current to the d-c moving coil to effectively oppose the change.

Fig. 2 shows the change in output resulting from a sudden application of a constant input to the dynamometer section. Curve *A* is the normal output that can be expected when the output circuit is a resistor. Curve *B* is the voltage drop, taken across an output resistor of 5,000 ohms shunted by a 5-μf (microfarad) capacitor. Curve *C* is the same as *B*, except for the capacitor which is 10 μf. These curves show that the response to a change is very rapid and the damping factor measured on the first overswing is approximately 3. Response time is approximately 0.3 second under normal conditions and can be reduced to 0.2 second by an external *R-C* network. The damping factor is also increased by the external network. The response time is considered more than adequate, since it is faster than the d-c instruments used to measure the output current and many times faster than the present dynamometer instruments having long pointers.

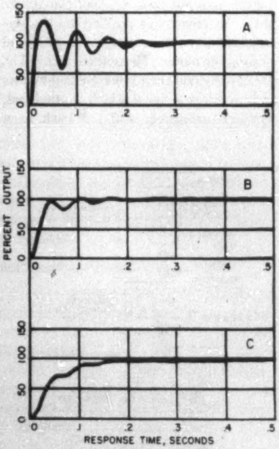

Fig. 2. Response time curves

A—Standard conditions
B—5,000-ohm 5-μf R-C network
C—5,000-ohm 10-μf R-C network

The product resolver unit with cover removed is shown in Fig. 3. The dynamometer element is not visible since it is surrounded by the ferrite shield held in place by the two upper straps. Below the shield can be seen the 200-kc field coils attached to the front section of the magnet structure. Two leveling screws and level are provided to properly level the unit.

The complete wiring diagram is shown in Fig. 4. The resolver unit is shown within the dotted lines. To the right of the unit is the amplifier, oscillator, and frequency discriminator with rectifier. To the left of the unit is the damping amplifier.

Briefly, the operation is as follows: The a-c voltage induced in moving coil (C_1-C_2) is impressed upon the primary of *T-101* where it is stepped up and is applied to the grid of the amplifier tube *V-101*. Here it is amplified in two stages.

The oscillator consists of *V-102* and the second stage of *V-101*. The tank circuit consists of the 200-kc field coils (F_1-F_2) in series with transformer *T-103*, both of which are tuned to cause the oscillator to oscillate at 200 kc with no input from the preamplifier. Regenerative feedback for the oscillator is by means of the *510k* resistor and the second stage of *V-101*.

The amplified voltage is introduced into the oscillator circuit. This voltage is essentially in quadrature with the oscillator feedback voltage (*510k*) and causes the oscillator frequency to change in order to maintain proper phase relationship for oscillation. The output voltage from transformer *T-103* feeds into a frequency discriminator as commonly used as a detector in frequency-modulated radio receivers. This rectifies the a-c voltage and produces a direct current which is a function of the oscillator frequency. This direct current is then fed back to the moving coil to develop torque to balance the system.

Damping is provided by an *R-C* network and a single-stage amplifier *V-701*. The amplifier responds to the d-c output current change by amplifying the voltage obtained from the *1k* resistor in series with the moving coil. The output of the damping amplifier provides a rate-of-change current which is fed back to oppose the input change of the d-c moving coil. The time constant of the circuit is controlled by the 0.1-μf capacitor and the circuit resistance.

Accuracy and Frequency Errors

Accuracy is determined by the design and stability of the dynamometer and d-c mechanisms. The stability of the amplifier is not a factor because the very high gain of the system and the large feedback ratio. This is a very important part of the design since the amplifier must not be a source of error. Its function is to supply and feed back sufficient current to balance the system. Aging of tubes or other changes which may change the amplifier gain merely cause the moving coils to deflect more than it did previously so as to maintain the same output current which is fed back to keep the system in balance.

The moving element consists of two round moving coils with a through shaft to minimize twisting as torque is applied to the coils. Four conducting filaments and mechanical balancing means complete the moving element to form a stable design. Since mechanical spring torque is not used, spring fatigue is not a factor. Stability has been obtained by conventional high quality design of the d-c and dynamometer elements.

Rated accuracy is 0.1% of full-rated d-c output. Ready means of adjustment to better than 0.1% is obtained by an ad-

justing screw which changes the position of a magnetic shunt on the d-c element magnet. Direct-current reversal errors are made negligible by a balance adjustment which compensates for residual magnetism in the surrounding magnetic parts.

The output current is directly proportional to the in-phase product of the input currents over a wide range. Calibration errors, as found in an instrument with a graduated scale, do not exist. For example, correction factors obtained from testing a wattmeter over a span of 100–500 watts showed a difference of less than 0.03% of reading.

The very slight movement of the moving element also makes it possible to keep the angle between the moving and field coils of the dynamometer element approximately 90 degrees apart at all times. The field-coil flux will thus cause little or no voltage to be induced in the moving coil. Since this induced voltage increases with frequency, it must be kept small in order to reduce the frequency error to a negligible value. This source of frequency error is called the mutual inductance error and has been effectively eliminated in the dynamometer by locating the moving coil at its point of zero mutual as described previously.

Another source of frequency error is caused by eddy currents circulating in the metal parts which are linked by the field-coil flux. This shows up as a lower indication as the frequency is increased since the eddy currents increase with frequency. It also causes the field-coil flux to lag the current producing it. The angular difference between the field-coil flux and current is called the current-circuit defect angle. This will cause an error in wattmeter indications at the lower power factors and must be kept small.

The eddy currents in the product resolver have been kept very small by surrounding the field coils with a ferrite shield and by using insulated strands of wire on field coils of few turns where a large cross section of wire is required. Most of the field coil flux is confined within the shield which has a very high resistance to eddy currents. As a result of this construction, the eddy current error has been kept very small.

A typical wattmeter was tested at the National Bureau of Standards to determine the difference between indications on alternating current and reversed direct current. The difference was undetectable at 60 cps, 0.03% high at 400 cps, 0.01% high at 800 cps, and 0.04% low at 1,600 cps. The current-circuit defect angle has been measured and is approximately 7 minutes at 2,500 cps, decreasing to a negligible value at 60 cps.

Other frequency errors are caused by the inductance of the dynamometer coils. This has been compensated and is described later for each type of measurement, i.e. voltmeter, wattmeter.

The accuracy of indication is also dependent upon the accuracy and readability of the output instrument. For the most precise measurements, the output current is passed through a precision resistor and the voltage drop is measured by a precision potentiometer. The direct current output is 1 ma at rated input and the output resistance can be any value up to 5,000 ohms. This provides ample power for accurate measurement and readability.

Friction errors are approximately 0.01% of rated output. This error has been kept low by maintaining a good torque-to-weight ratio of the moving element. It is also reduced further by the alternating torque always present from the 200-kc field. Because of these factors, it has been possible to use a pivot and jewel bearing design rather than a suspension design. Pivots are of high-quality steel and the jewels are of sapphire, spring-

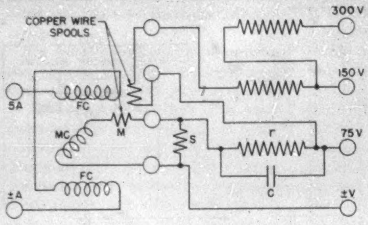

Fig. 5. Wiring diagram of wattmeter potential and current circuits

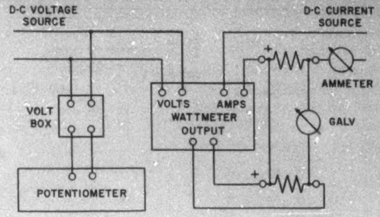

Fig. 6 (right). Connection for standardizing wattmeter using direct current, one potentiometer and two resistors

backed to eliminate damage to the pivots. This design is very satisfactory as evidenced by the negligible friction error.

In order to prevent wear of the pivots during shipment and later transportation, the moving element has been provided with a manual locking means so that it cannot move. The moving element locking means and the absence of a long pointer, subject to bending under unusual conditions, reduces the possibility of changes in accuracy during shipment.

Temperature and Sustained Operation Influence

Changes in temperature will change the resistance of copper-wound coils in the dynamometer mechanism and will change the flux in the magnet of the d-c mechanism. These will then cause errors in indication as the ambient temperature changes or as the coil resistance changes as a result of self-heating and heating of adjacent parts such as the series resistor. The effect of the changes in magnet flux with temperature is to increase the output approximately 0.016% for an increase of one centigrade degree in temperature. Copper resistance in the potential circuit of the voltmeter and wattmeter will cause the output to decrease for an increase in temperature. By proper selection of the ratio of copper resistance to total series resistance, it has been possible to make the potential circuit change approximately equal to the magnet-flux change and thus compensate for changes in ambient temperatures.

The sustained operation influence, or effect of self-heating, is also reduced to a very small amount as a result of the temperature-compensated design and also by the absence of spring fatigue since springs are not used. In addition, the product resolver unit is in a separate closed container completely removed from the series resistance and amplifier, both sources of heat. This, then, leaves the field coils in the product resolver unit as the main source of heat. The absence of appreciable deflection for the moving coil has made it possible to use a compact field coil shape instead of the usual round field coils of deflection instruments. This has decreased the power loss of the field circuit to approximately 0.18 watt whereas the conventional wattmeter has a power loss of approximately 0.8 watt. The reduced watts in the field coil and separation from other sources of heat accounts for a low value of sustained operation influence of approximately 0.03%.

External Field Influence

Shielding has been provided by a steel case around both mechanisms. In addition, a single wrap of 0.018-inch silicon steel has been added around the dynamometer mechanism. This has provided very effective shielding from external magnetic fields and the effect of a 5-oersted field is less than 0.1% of rated output when used on alternating current.

Voltmeter

The voltmeter uses moving and field coils rated at 50 ma for a multirange instrument of 300/150/75 volts. Series resistance consists of mica sheets wound with low-temperature coefficient resistance wire in a manner to be practically noninductive and capable of maximum heat dissipation. The d-c output is proportional to the output voltage squared.

Where required, frequency compensation is added by shunting the low-range series resistance with a capacitor. This method of compensation has been discussed in a prior paper.[6] Compensation is practically flat to 2,500 cps because of the low ratio of reactance to resistance in the potential circuit. Calculations for the 75-volt range show $X_L/R=0.26$ and $r/R=0.95$ at 2,500 cycles. From the curves of Fig. 4 of the referenced paper, the maximum frequency error is determined as less than 0.01%.

This compensation is also very exact for all outputs of the Inductronic voltmeter since the inductance in the potential circuit remains constant. The inductance of a dynamometer with moving and field coils connected in series is equal to L_m+L_f+2M, where L_m is the moving-coil inductance, L_f is the field-coil inductance and M is the mutual inductance between field and moving coils. In the conventional deflection dynamometer, the value of M varies as the pointer moves over the scale. The Inductronic dynamometer moving coil is at or approximately at the point of zero mutual inductance with the field coils and deviates so slightly from this position that the mutual inductance value M can be neglected. This leaves $L_m+L_f=$constant and hence, no change in potential circuit inductance. This means there is no scale error and the previously mentioned compensation for frequency at one scale point, or output in the case of the Inductronic voltmeter, will provide the same compensation at other scale points.

As a result of a low value of constant inductance, compensation can be very exact and the Inductronic voltmeter offers better than 0.1% accuracy from direct current to at least 2,500 cps.

Ammeter

Low current ranges of 15–150 milliamperes are provided by winding the moving and field coils with the appropriate turns and connecting them in series. Like the voltmeter, the d-c output varies as the square of the input current. If desired, the moving and field coils can be brought out to separate terminals and the instrument can then be used as a product resolver or current product meter.

Higher current ranges to one ampere are possible by means of a shunt across the moving coil. In order to keep the frequency and temperature errors to a low value, it is necessary to add resistance in series with the moving coil and shunt the combination. This requires approximately 5 volts across the shunt and makes ranges above 1 ampere impractical except by the use of a current transformer.

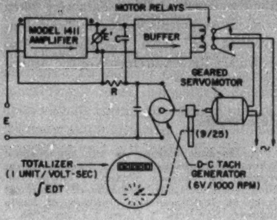

Fig. 7. Schematic diagram of the precision integrator

Wattmeter

The wattmeter uses a moving coil having a nominal rating of 25 ma connected in series with resistor sheets as used in the voltmeter. The field coil is wound for 5 amperes or lower.

In the section headed "Accuracy and Frequency Errors," it was explained that the eddy current errors are kept very small. Another source of error in the wattmeter is the defect angle in the potential circuit. This is caused by the inductance of the moving coil which causes the potential circuit current to lag the applied voltage by an angle equal to $\tan^{-1} L_m/R$ where R is the potential circuit resistance and L_m the moving-coil inductance. This can be compensated by shunting the series resistance with a capacitor computed from the equation $C = L_m/r^2$. This equation is given in reference 6, where r is equal to the resistance shunted by capacitor C. This compensates for the potential-circuit defect angle leaving the current-circuit defect angle caused by the eddy currents.

This angle can be compensated by shunting the moving coil with a very high resistance as shown in Fig. 5.

Let

I = current coming into shunted moving coil circuit
i = moving coil current
M = total moving coil resistance which is shunted
S = shunt resistance
X = moving coil reactance at the compensated frequency
θ_s = phase angle between I and i

$$i = \frac{IS}{S+M+jX} = \frac{IS(S+M)-jISX}{(S+M)^2+X^2} \qquad (1)$$

$$\tan\theta_s = \frac{j \text{ terms}}{\text{real terms}} = \frac{-X}{S+M} \qquad (2)$$

This is then the angle by which the current in the moving coil lags the applied current in the potential circuit. The current-circuit defect angle is also lagging and by making the shunt angle θ_s equal to the defect angle, the over-all defect angle is zero.

This compensation of both potential- and current-circuit defect angle can be very exact to as high as 2,500 cps since the error and compensating means vary directly with frequency, thus making compensation possible over the complete range.

It is very important that the defect angle be reduced to a negligible value when low power-factor measurements are made. For example, an over-all defect angle of 2 minutes will cause an error at 10% power factor of 0.6% of reading.

The negligible defect angle makes the Inductronic wattmeter ideal for low power-factor measurements. In addition, the low power loss in the field coils makes it possible to overload the field coils four times their rated value. It is also possible to use a d-c output indicator having a full-scale range of 0.2 ma instead of 1 ma. This provides full-scale readability at 5% power factor. The accuracy will not be the same as that obtained with full-rated output, however, it can be held to 0.5%.

The wattmeter can be standardized on direct current by using a precise voltage source and two four-terminal resistors or shunts, see Fig. 6. One shunt is connected in series with the current circuit and the other is connected across the d-c output terminals. The two shunts are connected together so as to compare voltage drops by means of a sensitive galvanometer. Direct current of the approximate value desired is applied to the field coils and a direct voltage is applied to the potential circuit. This voltage is varied until the galvanometer between the shunts reads zero. The error is then the difference between the voltage applied and the rated voltage. Changes in current will not affect the balance since the voltage drop on both resistors will go up and down together for changes in current. By this means, the wattmeter can be standardized by using one precision potentiometer.

Watt-Hours

Watt-hours are measured by connecting the output current of the wattmeter to a resistor to provide a millivolt drop of 0–50 millivolts. This voltage is then applied to a precision integrator which measures the time integral of the voltage.

Such an integrator is shown in Fig. 7. Input voltage E is applied to the amplifier which produces an output current proportional to the input millivolts. This builds up a voltage E' across the capacitor C. When the voltage build-up is sufficient to operate the motor relay, it starts the motor connected to the d-c tachometer generator. The generator produces a voltage greater than the input voltage which causes the amplified output to reverse. This discharges the capacitor and, at a lower voltage the motor relay opens and the generator stops. The voltage again builds up and the cycle is repeated. The revolutions of the generator are totalized on a counter geared to the generator.

The equation for the volt-second input is

$$Edt = RCE' + k\theta$$

where

E = input voltage, volts
dt = input time, seconds
R = resistance, ohms
C = capacitance, farads
E' = amplifier output voltage, volts
k = generator constant, volts per rps (also volt-seconds per revolution)
θ = rotation of generator in revolutions

Since R and C are constant, the volt-seconds are measured by noting the voltage E' recorded on a voltmeter and the generator revolutions given on the counter. By suitable calibration and selection of constants, the meter and counter are calibrated in terms of volt-seconds, watt-hours, etc.

For long periods of time, such as 10 minutes or more, the volt-seconds stored in the capacitor at the end of a cycle do not have be read on the voltmeter. This

Table I. Summary of Wattmeter Characteristics

Requirement	Inductronic Wattmeter	ASA C39.1
Rated accuracy, % of full scale	0.1	0.1
Damping factor	3	2.5 min
Response time, seconds	0.3	10 max
Loss, volt amperes:

Voltage influence ±10% variation, %	less than 0.01	0.1 max
Power factor influence, 1.0–0.5 pf, 60 cps, %	negligible	0.1 max

* The error allowed is for a lesser change to 54–66 cps from 60 cps.

is because the counter indication is large and the small amount of volt-seconds indicated on the voltmeter can be neglected. For shorter periods of time, the sum of the voltmeter and counter readings should be added together to give the total volt-seconds.

The basic accuracy for normal periods of time (10 minutes or more) is completely dependent upon the stability of the generator. This stability has been obtained by good design practice and 0.1% accuracy is maintained. For short periods of time, the accuracy of the instrument and readability of the counter are a factor and must be considered. A more complete description of the precision integrator is given in reference 7.

The combination of Inductronic wattmeter and integrator has been tested under actual field conditions to determine its suitability for measuring turbine efficiencies. This test was performed by the engineers of the Long Island Lighting Company at their Barrett Power Station.

Five tests were run with indicating wattmeters in each of three phases and with one Inductronic wattmeter and integrator in phase A. The test time varied from 1–3 hours. The integrator was read at the beginning and end of each test and the wattmeters were read every minute.

The largest difference between the two watt-hour readings by each method was 0.12%. The average difference for all five tests was 0.08%. It is believed that using Inductronic wattmeters in the other two phases and feeding the output to three integrators, would have provided total generator output in kilowatt-hours to a accuracy of approximately 0.1%. The output of the three wattmeters can also be connected to one integrator to provide the total 3-phase energy. This may not be convenient, where transformer correction factors must be applied for each phase and where it is desirable to know the load balance.

Conclusions

The product resolver can be used for the measurement of volts, amperes, watts, and watt-hours when used in conjunction with a precision integrator. It offers 0.1% accuracy over a wide power-frequency range and provides a d-c output which can be measured or used for control. Summarized in Table I are some of the important characteristics of the Inductronic wattmeter. These data were taken from measurements made on a typical instrument or from calculation. Also shown are the requirements of the American Standards.[8]

Polyphase Meter Connections 30 Years After Woodson

F. W. WARBURTON
MEMBER AIEE

Synopsis: In 1928, W. C. Woodson announced his procedure for verifying instrument transformer connections to meters for 3-phase 3-wire services.[1] The Woodson method has earned the reputation of being the most reliable and satisfactory practice for proving these connections. In 1928, the procedure had minor limitations. Since that time, the employment of 3-phase 4-wire distribution systems, the growing impracticability of reducing customer loads for connection testing to balanced 3-phase known impedances, and the increasing use of capacitors have caused difficulty both in proving internal meter connections and in estimating the load phasors needed for comparison with the Woodson phasors obtained at the meter test switch. There is no procedure that will signal a definite "no" or "yes" that meter test switch phasors correspond to load phasors. On the contrary, the matching of load and Woodson phasors is entrusted to human judgment, and errors are probable. On one utility system, 3$^1/_2$ stator Woodson kits, used in proving over 1,500 complex metering installations, have given added but not complete insurance for verifying 4-wire Y systems. Thirty years of electrical growth and changes have increased the limitations to proving transformer-connected meter installations. In the meantime, there have been no adequate new or extended procedures to give required integrity in this area of metering.

THE METERING of large customers of electric power utilities involves the use of potential and current transformers with secondary connections to the meter. Depending upon individual company practices, and whether 3-wire or 4-wire service is provided, usually five to eight current and potential-transformer secondary conductors are connected to the meter test switch. In making connections with these transformer secondaries, several errors are possible; wrong transformer ratio or polarity, transformers connected in or to the wrong primary conductors, transformer secondary connections reversed, grounded, opened, or short-circuited. The possibility of error is increased by making installations under emergency conditions, the use of nonstandard materials, incorrect reconnection of leads opened during a test, and the absence of key personnel. Another possible contribution to error is the fact that most metermen consider that each stator of a 3-stator meter on a 4-wire Y system always should cause the disk to run in a "forward" direction.

Electric power companies, soon after

Paper 59-168, recommended by the AIEE Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted August 14, 1958; made available for printing December 2, 1958.

F. W. Warburton is with the New England Power Service Company, Worcester, Mass.

The author appreciates the contributions, in both data and ideas, of his colleagues G. A. Palmer, L. S. Salmonsen, and J. F. Stasaitis of the New England Electric System.

installing or modifying metering facilities to their large energy-taking customers usually have a specialist make a verification check of instrument transformer connections. To uncover any faults in the connections, some companies depend upon visually tracing the wiring and making meter stator tests with use of customer equipment for a test load. For this purpose, wire coverings can be colored or have printed number identification. The new plastic-sheathed conductors offer good legibility, with promise of more permanence than has formerly been obtained. However, because of pole-top-mounted transformers, concealed wiring, wrong nomenclatures, human errors in tracing wires, and hazards to employees, other companies have substituted special checks, such as the Woodson method applied at the meter test switch, as the best means to insure integrity of connections.

Since internal meter connections also can be improper, the connection verification checker in many companies proves meter-coil integrity as well as the wiring to the instrument transformers. For complete audit, a meter calibration test, register proving, and a register-multiplying constant check are required. This study attempts to show that current practices used for verification of connections are not precise operations and that the laws of probability point to serious, if infrequent, errors.

The ultimate purpose of the Woodson procedure or other connection verification is to insure correct billing to customers. If a utility should install a meter with an improper instrument transformer connection and subsequently "approve" it by a Woodson or other test, the error in billing could continue indefinitely. This situation results because generally there are no previous bills suitable for comparison and most line loss studies, if made, must be more nearly exact than is normally practical to uncover such an error. As a consequence, the mistake may well continue for the life of the installation, a period that may cover 25 years or more. A discrepancy exceeding several million kilowatt-hours a year may fall in this category.

Since a watt-hour meter measuring energy at the usual balance of load and at a power factor of 0.7 lag to 1.0, normally causes highest registration when connections are correct, it is not surprising to find that nearly all connection errors penalize the supplier of energy. On one system, eight connection errors uncovered over a period of 5 years were all causing low measurements; when they were corrected, an estimated $60,000 was added annually to energy revenue.

For brevity, the discussion except where noted will assume that: metering follows Blondel's theorem; no instrument transformer secondary conductor is employed for both "potential" and "current" use; meter test switches are inserted immediately before the meter and at the terminations of the instrument-transformer secondary conductors; only the original Woodson procedure for instrument-transformer connections and the more popular meter stator test procedures are employed; the common and grounded point of the current-transformer secondaries is or can be made available at the meter test switch.

The Woodson Method

OBJECT

The Woodson contribution to metering is a procedure whereby opportunity is presented for a tester and any reviewing engineer to decide whether the phasor diagram constructed from currents and voltages measured at the meter test switch agrees or does not agree with the estimated load phasors. If the Woodson and load phasors are in agreement, the connections from the primary supply will provide the metering quantities, in proper magnitude and order, to the meter test switch. However, as yet no mechanical procedure proving the correctness of the diagram construction can supply proof that the diagram agrees or disagrees with the load phasors. The question of agreement must be answered by man. As already stated, the serious present weakness of the system is the occasional difficulty in estimating load phasors with required accuracy.

SCOPE OF TEST PROCEDURE

Woodson necessarily used contemporary meter test procedures to supplement his check of transformer connections and he thereby determined the soundness of the complete metering installation. Thus Woodson's procedure concerned transformer connections only, but to provide an acceptable degree of assurance that energy and power registrations are satisfactory, it is also necessary to trace connections between meter switch and meter, verify internal meter connections, check meter registration, determine instrument-transformer performance, and ascertain correct multiplying constants. In the author's company, watt-hour meter constant and conection accuracy tests comprise: meter current coil continuity, single stator, and Ackerman tests; Woodson "star connection" wattmeter checks against meter disk revolutions; establishment of the phasor diagram of currents and potentials at the meter test switch; comparison of this diagram with the estimated load; decision as to correct, incorrect, or inconclusive connections; calculation of multiplying constants; inspection of instrument transformers to ascertain proper capacity and relative location of conductor connections; inspection for safety, approved devices, utility of layout, and possible diversion of energy. These are all accomplished at the meter installation. Later, instrument-transformer test record cards are screened at the operating company office.

PERTINENT PARTS OF TEST PROCEDURE

The installation from meter switch through the meter is first checked. The initial test item is an "as found" visual inspection of meter type, disk speed, and disk direction of rotation. Watt-hour meter dial reading, maximum-demand deflection, and meter nameplate data are recorded on the Form I work sheet in Fig. 1. The second step is a tracing of connections between test switch and meter. Here, the most trouble is encountered when switch connections are not made as specified in the standards. Occasionally, poor switch action will cause difficulty.

Next, partial integrity of the meter is investigated. Action depends upon the type of meter, the load, and the preferences of the tester. The object is to test for coil opens, grounds, reversals, interchanges, and disk constant. Here a 2-stator, *A* and *C* meter with 3-phase 3-wire delta service is assumed. The first step is a combined proving of meter coil continuity and a stator check. A suitable meter test switch would have potential blades *A*, *B* (common), and *C;* current blade pairs *A* and *C;* or a total of seven subswitches. All meter switch blades except potentials *A* and *B* are opened. Woodson current plug *A* is inserted in current series jack *A*, short-circuit current blade *A* is closed, and the Woodson ammeter observed. Also, for economy of motion, current plug *C* is inserted in current series jack *C* at this time, but short-circuit switch blade *C* is not closed. All three potential leads *A*, *B*, and *C* are clipped onto the line side of the respective meter potential switches *A*, *B*, and *C*. Meter disk rotation and wattmeter and ammeter usually indicate continuity of circuitry and "proper" meter-stator *A* performance. Similarly, continuity of

meter coil *C* and performance of stator *C* are checked. However, if the disk does not turn for either stator *A* or *C* the tester must determine whether a potential coil is open; or one stator is operating at power factor = 0.0; or the load is essentially single-phase and current in *A* or *C* is insufficient to turn the disk. The continuity of the two potential coils can be determined by the Ackerman check. In this test all switch blades except potential *B* are closed and line voltage *AC* is placed across the 2-meter potential coils in series. Currents from transformer-secondary conductors *A* and *C* are supplied to meter coils *A* and *C* respectively. If the disk turns, continuity of both potential coils is assured. Also, if the disk speed increases with later closing of potential switch *B*, added insurance to verification of connections is made.[2] Single-phase loading can be determined from the Woodson ammeter measurements. A power factor of zero per cent will be substantiated by the Woodson diagram.

The meter disk constant test usually follows. The Woodson kit is used as a wattmeter to indicate flow of power to the meter. All meter test switch blades, except the two "jacked" units, are closed with current plugs *A*, *B*, and *C* and potential clips *A*, *B*, and *C* still connected to the switch from the preceding test. For the period of from one to perhaps ten disk revolutions, depending upon load conditions, the Y (star) connection watt meter watt-seconds are calculated, recorded, totalled, and matched against the meter disk constant. If agreement between meter performance and Woodson measurements is not within 5% the run is repeated.

Woodson Phasor Diagram

The phasor diagram data are next obtained as a step in proving connections between the instrument transformers and the meter test switch. To measure these data quickly and easily, Woodson devised his "kit." It usually, for 3-wire services, comprises a voltmeter, three identical wattmeters with multipliers, an ammeter, a phase-sequence indicator, and required switches in a single "black box." The switches reverse polarities and arrange connections in Y or in series. The normal practice is to connect the potential coil leads of the wattmeters to the three potential switches, which are connected in turn to the potential-transformer secondaries. In the 3-wire delta service, this means that the kit wattmeter potential coils are connected in Y to the delta of line potentials *AB*, *BC*, and *CA* as shown in Fig. 2(B). The neutral of the Woodson Y, although not needed in this case, is accessible on the kit for connection purpose. In Fig. 2(A), with a 3-phase delta service, the 3-wattmeter voltages are assumed to be 120 degrees apart, as shown by E_{cn}, E_{bn}, E_{cn}, and are used with kit wattmeters *WMA*, *WMB*, and *WMC* respectively. The assumed secondary load currents I_a, I_b, and I_c are in turn switched through each of the three wattmeters and the single ammeter. Values of current and watts are recorded. This constitutes Woodson's series-connection test.

All service voltages available at the meter test switch are next measured by the kit voltmeter and recorded. If unbalanced or abnormal values are obtained, the investigator is alerted to take additional tests, such as checks for grounds on the potential circuitry or as indicated in the section "Load Voltage Unbalance." Phase sequence is then ascertained and recorded.

In Fig. 2(A), when I_c, with a value of 0.866 ampere, flows through *WMA*, the reading is −30 watts; through *WMB* −30 watts; and through *WMC*, +60 watts. With balanced voltages, E_{an}, E_{bn}, and E_{cn}, the wattmeter readings are proportional to the watt components of the currents I_a, I_b, and I_c. This voltage balance and associated current and watt proportionality permit the phasor diagram to be determined by plotting the wattmeter readings to scale on the voltage phasors. Thus, to determine I_c, −30 watts, representing the watt component of I_c, is plotted to a convenient scale along E_{an}. This actually is +30 watts along $-E_{an}$. At this point a perpendicular *r-s* is constructed. I_c must lie at some point on this line *r-s*. Likewise, with +30 watts plotted on $-E_{bn}$ and +60 watts on E_{cn}, I_c must also lie at some point on these respective $-E_{bn}$ and E_{cn} perpendiculars. It will be noted that all three perpendiculars, *r-s*, *m-s*, and the one erected on E_{cn}, meet at a point. The intersection of the three perpendiculars is

I_c. The currents I_a and I_b are determined similarly. If all three perpendiculars establishing a current phasor do not intersect at a point, either the load has changed during the time the measurements were taken, or some trouble exists in assumptions of voltage phasors or in the mechanics of obtaining and plotting data. Arithmetical checks to nearly zero of the wattmeter tabulations, both horizontally and vertically, are assumed to signify that the load did not change during time of measurement and that the mechanics of making readings and entering table data are correct. The facts that wattmeter tabulations add to zero and that all three perpendiculars do meet at a point are not proof of proper connections, as further explanation will demonstrate.

Since three balanced voltages, E_{an}, E_{bn}, and E_{cn}, are assumed in the Woodson procedure, work sheets can be printed as shown by Form I, with the voltages 120 degrees apart. Actual cases, deviating from this balanced condition, will result theoretically in failure of the three perpendiculars to meet in a point. Experience with thousands of field cases on 3-wire delta systems shows the degree of such failure is not significant. Effects of voltage unbalance on types of services other than 3-wire delta are discussed later.

When the phasor diagram has been constructed, it is inspected for agreement with previously obtained data. For example, if, during the stator tests, one stator of the meter failed to rotate the disk the diagram should show either a nearly 90-degree relation between the respective stator potential and current, or a negligible a or c current. In case of doubt the stator tests are repeated. Ampere values in the data table are compared with diagram current phasor magnitudes. Diagram current phasors should theoretically add to zero and they are visually checked for this total. Wattmeter readings are totalled and compared to the recorded amount from the disk constant registration test. Observe that the diagonal addition, Fig. 2(A), table measurements of +30 *WMA*, +60 *WMB* and +60 *WMC* total 150 watts.

The tester next compares his judgment of load phasors with the diagram. In case of doubt about the load-diagram match, a repeat test with known load or known load change, or a visual checking of transformer connections are considered. If the operator is not satisfied by these extra measures, decision on the match of diagram phasors with load phasors is delayed until a repeat test under favorable conditions can be made.

REGISTER GEAR, BURDEN TESTS, AND OTHER FACTORS

To verify correct meter billing, the meter disk constant tested previously, the register gear ratio, and the transformer ratios are independently checked by the operator. The register ratio proving is delayed until this time in order not to disturb the "As Found" operation of the meter. The register is now removed and its performance determined on a separate device. If a mechanical demand meter is included in the installation, disk revolutions are matched against pointer deflection. The timing motor, if action is suspect, is tested for a period of one minute. The pusher pointer reading of a thermal demand is compared against the watts load.

A few installations have kilowatt and kilowatt-hour totalizing features. This requires checking of all contact devices, relays, auxiliary demand devices, and impulse values, and establishing proper transmittal to the end indication.

Relays and other nonenergy metering devices connected to instrument transformers may prevent opening of their circuits and thus complicate connection verifications. The meter-multiplying constant is not verified until transformer nomenclature, recorded at convenience during the test, is later checked with office records of transformer-acceptance tests. At this time, test-accuracy records of the transformers are reviewed.

Many users incorporate a current-transformer burden tester in the Woodson kit. The most economical time to use this on transformer secondary and meter-current circuits *A*, *B*, and *C* is while the wattmeter table data are being obtained for currents *a*, *b*, and *c*, respectively. The burden-tester gives indication of many major defects in the instrument transformers, and it should detect most grounds in the meter and transformer connections. Any ground fault with approved standard circuitry not sensed by burden test, should cause only a small meter error.

Instead of a "kit," three separate meters, one voltmeter, one ammeter, and one wattmeter, are sometimes used to obtain the Woodson data. This does not change the procedure in principle but increases time of testing. Time of testing is important because loads change and the more quickly data are obtained the greater chance there is of all readings representing the same load, a requirement for a firm diagram.

In the author's company, the watt-hour meter constant and connection accuracy tests (Fig. 1) of an installation call for removal and replacement of the register. This in turn automatically demands, at a later date, a meter calibration test.

PROCEDURE SUMMARY

Assuming standard circuitry, normal balance of voltages, and a known load, but with the limitations as shown by examples described later, the Woodson procedure enables the operator to give quick and accurate decision on the correctness of transformer connections to the meter test switch. The major key to trouble in this statement is the term "known load." Procedures other than the Woodson are necessary to complete the verification of the installation by proving the meter and connections thereto from the meter test switch. Only one of these tests as described later is infallible.

Discussion of Limitations

In 1928, the relative simplicity which was required to prove instrument-transformer connections by the Woodson method facilitated judgment and made the procedure almost foolproof. However, two assumptions were necessary. Woodson stated that the load power factor should be known in order to be within 60 degrees of the diagram phasors, and that it should be known as to whether they are leading or lagging.[1] Knowlton also described limitations.[2] Kouwenhoven, in 1916, argued and Woodson in 1928 implied, that any industrial meter installation could be tested when only a 3-phase motor was operating, thus obtaining a balanced load with a lagging power factor capable of being estimated within the 60 degree requirement.[1,3] Accordingly, on 3-wire delta systems, with the exception of the 3-wire version of example 4 described later, the Woodson check in 1928, when the precautions its author cited were followed, could give extremely good security.

Today most energy takings cannot be reduced to a simple balanced 3-phase load because of their nature or because customers do not desire to stop production during normal working hours. Hence, in many cases the Woodson tester is forced to accept an "unproved" load for his test condition and thus falls short of making the firmest possible check. This is the most important factor in restricting the accuracy of the Woodson method.

Since 1928, 4-wire Y, 4-wire delta, and network systems have become increasingly prevalent. The Woodson kit was originated to be used in 3-stator check of a 3-wire delta system. The phasor diagram data obtained at the meter switch established the three currents at the meter switch. Nine wattmeter readings were required to determine these currents independently and afford a check to the operator's work. Correspondingly, to determine the correctness and verify the four current phasors of a 4-wire systems at the meter switch, 12 wattmeter readings are necessary, 16 desired; any fewer than these degrades the test.

The question probably arises as to why one more stator is needed for the kit than is required in the corresponding meter where Blondel's *N*-1 theorem is applied. The answer lies in the fact that the kit does not measure power or energy as an end result but measures the quantities needed to construct a firm phasor diagram. A firm diagram requires two intersecting perpendiculars to determine a current phasor, and a third to prove that the operator made no significant mistake in obtaining data and plotting it. This means that the kit must measure one current and three wattmeter quantities for each current phasor to be established. Establishing all currents on the phasor diagram from measured data permits examination of their vector addition to zero. This control is necessary to decrease the possibility of human error in constructing the diagram. Thus, if the neutral current of a 4-wire 3-phase Y is not constructed from wattmeter measurements but is obtained from vector graphical addition of the 3-phase currents of the diagram, it is impossible to ascertain complete soundness of the operator's work in making the diagram.

FOUR-WIRE Y

Because of the difficulty of utilizing the neutral-to-ground voltage for wattmeter measurements only $3^1/_2$ stators appear practical for use on a 4-wire Y system. This means twelve wattmeter readings obtained with four conductor currents and three voltages to the kit neutral. The lack of the four wattmeter readings obtained with the neutral-to-ground voltage means that the neutral-to-ground voltage phasor cannot be constructed and checked by inspection for consistency of measurements, reasonable phase position, and addition to zero with the 3-Y voltages.

FOUR-WIRE DELTA

It might appear that in using the 4-wire delta system there would be available four test currents and four or more usable potentials, making possible the construction of a diagram of phasors. However, actual metering practices applied to 4-wire delta may prohibit a good Woodson check. This depends upon the voltages and currents available at the meter test switch from the instrument transformers. If three primary conductor currents of a 4-wire delta are provided at the meter test switch, the fourth current can be measured by summation in the kit. If, in addition, three voltages from the potential transformers are available at the meter switch, it is possible to construct a diagram with three intersecting perpendiculars to determine each of the four current phasors. If the three available potentials are the conductor-to-conductor voltages, they form a closed polygon and their sum is zero; this affords vertical and horizontal checks to zero of measurements in the wattmeter table. If the sum of any three meter switch potentials is zero or nearly zero, normally this also assures wide phase-angle separation, a requirement for accurately locating the intersection of diagram perpendiculars. If the three potential points are the corner vertices of the delta, the kit potential coil voltages will be the balanced E_{an}, E_{bn}, E_{cn} Y of the 3-wire delta; see Form I (Fig. 1) and example 1 in Fig. 2(A). Metering potentials, of course, need not be these Y voltages, but in any case the metering potentials could be drawn on the work sheet form similarly to the 2-stator metering voltages E_{ab} and E_{cb} of Form I. In actual practice, with a 3-stator meter or with one form of the $2^1/_2$ stator meter, if the three delta-vertice potential points and 3-conductor currents are available at the meter test switch, a satisfactory diagram can be established. However, another 4-wire delta metering method uses a 2-stator meter with totalized sensing of two conductor currents by the use of one stator. This generally affords only three potentials and one separate conductor current at the meter test switch, forbidding a diagram or a single, simple stator test. Consequently, ability to prove connections should be a consideration in choosing a meter.

SYSTEM VOLTAGE SUPPLY UNBALANCE

Unbalanced supply voltages were not discussed in the NELA 1928 Woodson paper.[1] There are two types of voltage unbalance, one caused by loading and one by design of the voltage supply. The latter type is exemplified by the 4-wire delta, by the 2-phase 3-wire supply, and by the 120-120-208-volt service where only three wires of the 4-wire network system are used. As with Woodson's original 3-wire delta arrangement, all other services require that voltage phasors be assumed for diagram plotting. As previously stated, these voltage phasors are the nominal voltages existing across the identical potential coils of the kit. Woodson plotted "kit" watts along the three balanced Y kit voltage phasors E_{an}, E_{bn}, and E_{cn}, which were assumed from connection of the kit to a delta system. This was permissible only because the potentials of his three wattmeters were equal.

Explanation of the use of watts as a phasor quantity was not given in the Woodson paper.[1] This explanation is required, however, to understand application of the Woodson method to unbalanced voltage services. Working backward from the completed phasor diagram example 1, Fig. 2(A), it will be seen that the distance *n* to *r* is actually the watt component $I \cos \theta$ of I_c on the voltage phasor $-E_{an}$, where θ is the included angle between $-E_{an}$ and I_c. This length

(B)—Woodson phasor diagram

nr is then a measure of amperes. It will be remembered, however, that nr was also by construction $+30$ watts along $-E_{an}$. Hence, from this analysis, $nr=+30$ watts $=-E_{an}\,I\cos\theta=I\cos\theta$ amperes, or watts are equated to amperes. The explanation of this fallacy lies in the fact that watts are not a phasor quantity and for this specific purpose $+30$ is a numeric scale distance obtained by multiplying $I\cos\theta$ in the wattmeter by the numeric $-E_{an}$. Now, to be precise, I_c is established from perpendiculars erected at the end of the three scaled watt components of I_c on the three phasors, $-E_{an}$, $-E_{bn}$, and E_{cn}. The watt components of I_c are determined by the load power factor and the load in amperes. They are multiplied by their respective voltages (numerics) in the wattmeters. It follows that if the watt table values are to have the same plotting scale, the wattmeter voltage multiplying factors must be equal. If the scales are different, the constructed perpendiculars will not meet in a point. By this analysis it should be clear that unequal wattmeter voltages call for adjustment of wattmeter values used for plotting. It should also be clear that the potentials along which the wattmeter values are plotted should be the potential phasors across the wattmeters.

Illustration of wattmeter value adjustment for constructing diagrams is offered in example 2, Fig. 3, which has a 120-120-208-volt 3-wire network service. The voltages across the wattmeters, as shown in Fig. 3(B), are 105.8, 105.8, and 40.0 volts. These values were determined by assuming nominal 120-120-208-volt supply and establishing the usual three simultaneous equations for solution of a balanced Y load. Graphically it can be proved that the Y voltages lie along the medians to the 120-120-208 triangle. Three ways are cited to obtain comparable scale watt values for plotting. The watt values, if divided by their respective voltages 105.8, 105.8, and 40.0 volts, will give the respective ampere in-phase currents or equalized plotting values. Or, the 40.0-volt, E_{n0} watt readings, namely -20, -20, and $+40$ watts, may be multiplied by 105.8/40.0. A simplification to avoid manual multiplication would be to incorporate the multiplication by means of different scale divisions on the voltage phasors printed on the work sheet form. This scheme is used in Fig. 3(B). Observe that the scale graduations for plotting watts from the data table along E_{n0} are 105.8/40 times as long as the scale along E_{a0} and E_{c0}. Actually this was readily accomplished by making a scale along E_{n0} 100/40 times a scale along E_{an} and E_{cn} and dropping perpendiculars from E_{an} scale markings to E_{a0} and from E_{cn} to E_{c0}.

Fig. 3(B) is a composite of the load phasor and the kit phasor diagrams. It is not correct in that when one diagram was superimposed on the other, points N and O, having a potential difference of 40 volts, were joined. This is permissible because, for the restricted purpose of the test no errors are made. However, the liberty taken permits easy construction and inspection of the meter test switch current and potential phasors in their proper phase sequence. Observe, as in the balanced delta and Y services, that current vectors add to zero on the diagram and are proportional to the measured values in the Woodson data table.

Similarly to the network system, if a

120-volt–120-volt–169.7-volt 2-phase 3-wire service is used, the Woodson nominal Y voltages are 89.4, 89.4, and 56.6 volts with 108.5 degrees separation between each pair of 89.4 volts, and the 56.6-volt phasors and 143 degrees between the two 89.4-volt phasors. This, of course, presumes identical potential coil impedances in the kit.

The 4-wire delta service has previously been analyzed in part. If metering follows Blondel's theorem, a review of proposed metering methods shows that the three Y potentials of the delta and all four primary currents may be sensed by the kit, permitting use of the three plotting potentials of Form I regardless of the particular voltages applied to the meter. Since Woodson's three required perpendiculars per current phasor depend upon the potentials and currents available at the meter test switch and not at the meter, even if Blondel's theorem is not used in selection of the meter it still may be possible to construct a firm diagram to represent test switch quantities. In the latter case, whether a special work sheet form is required would depend upon the particular conductor potentials and currents available to the operator.

Regardless of the service, experience and the use of appropriate Woodson work sheet forms make dissymmetry of potential supply a minor matter as far as the mechanics of obtaining a phasor diagram are concerned.

LOAD VOLTAGE UNBALANCE

Unbalanced voltages caused by load should always be considered a danger sign, although only occasionally are they liable to result in improper verification. A review of several hundred metering installations on 4-wire Y systems was made to help determine the practical influence of load voltage unbalance in proving connections for this type of service. System neutral conductor-to-ground voltages were found to be as high as 4 volts in congested areas and as high as 14 volts on long rural lines. The study indicated that the danger resulting from unbalance was slight where approved primary distribution connections were made. However, example 3 (Fig. 4) with only a few volts unbalance, represents a case of a nonstandard distribution connection and emphasizes the need of vigilance in testing. The study also resulted in the conclusion that for 3-wire and 4-wire Y services, printed work sheets such as Form I, with 120-degree spaced voltage phasers and normally obtained Woodson data could be used, if operators had a high degree of competence, for constructing phasor diagrams without danger of approving wrong connections.

At this time, the reader is requested, before reading further, to decide if the phasor diagram of Fig. 4(A) represents correct connections for single-phase and 3-phase induction motors. The as-found meter connections of Fig. 4(A) are correct, as the voltages and currents in the supply meter side of the transformer were as shown. In contrast, the customer's load phasors were those of Fig. 4(B). The difference is caused by the questionable neutral-to-ground connection on the Y primary of the supply transformer, together with the unbalanced supply voltage. Overloading of the distribution transformer with zero phase-sequence cur-

rents results. Thus, although meter connections are correct, transformer and supply line currents are increased and the customer is charged with unnecessary transformer losses. When this questionable connection was removed the excessive transformer losses did not appear and only the customer's normal load was measured by the meter.

Observe the reverse power of meter stator *B* in the as-found table of Fig. 4(A). Note that the actual customer's current phasors or the as-left Fig. 4(B) phasors are the as-found phasors minus one third of the neutral or zero-phase-sequence current. There is temptation for the installer or a verification tester to make all stators "run" forward, thereby establishing an incorrect connection. Observe that if the voltages were balanced at the time of testing, the questionable connection would not be discovered. The vertical table totals under *A*, *B*, and *C* should not theoretically be zero but they were within the accuracy of measurements. Wattmeter table data in this example were obtained with a 3-stator kit and the total values were established by operator addition, not by measurement. Consequently, the positive horizontal check to zero of wattmeter values is missing.

Any potential unbalance of over a few volts, especially when combined with a watt table unbalance should be investigated to determine whether zero-phase-sequence currents are responsible or if instrument transformers have improper ratios or faulted connections. The example is not illustrative of a Woodson limitation. It is included to show the superiority of Woodson over meter stator checks. As this paper was about to be submitted for publication a second case of this questionable connection and I_b reversal was uncovered. A 3-phase induction motor operating on badly unbalanced 3-wire 3-phase supply voltages will show a similar I_b reversal.[4]

Except for the case of the badly unbalanced supply to an induction motor, the effect of voltage unbalance caused by load on 4-wire delta services does not appear, by inspection, liable to cause improper "verification of connections." However, the author has no experience with proving installations with this type of supply.

OTHER CONSIDERATIONS

Instrument transformers connected 3-wire Y-primary, 4-wire Y-secondary, may give some 12% overvoltage on the secondary as a result of the suppressed third-harmonic magnetizing current. This overvoltage is not indicative of a wrong connection but it does present need for matching knowledge and reasoning by the Woodson operator.

In increasing instances the addition of static capacitors to power systems has caused difficulty in determining whether the power factor is lagging or leading. Especially is this true of single-phase capacitors where primary capacitor phase and corresponding secondary metering phase cannot readily be paired. For illustration, single-phase welders with concealed internal capacitors may cause disturbing phasor diagrams especially on unbalanced system voltage supplies. For the effect on a balanced 3-wire delta service observe the example on Form I (Fig. 1). Likewise, the practice of ganging "leading-power-factor" fluorescent lights on one phase and "lagging" on another presents a hazard to proper verification. Up to 30% of third harmonic and its multiples in fluorescent-lighting phase conductors can also cause confusion to the operator. Saturable reactors used for

Vol.
Pt. 1
1959

voltage control can cause current to be practically all harmonic with confusing results to an operator. The interconnection of systems and customer generation with tie-line metering installations, together with standards of operation which do not permit Woodson operators to open such interconnections, again create the hazard of unknown load power factor. For illustration of some of these factors examples follow.

EXAMPLES OF WRONG TRANSFORMER CONNECTIONS

All examples described in this paper were found on the author's system. A total of 13 incorrect transformer connections in 5,000-meter installations were uncovered during the years 1947–1957. In the wattmeter tables, except for example 3, Fig. 4(A), nominal rather than actual voltages are given. Excepting example 6, wattmeter values in the tables are rounded out to give horizontal and vertical checks to zero, whereas in practice there may be minor discrepancies.

Example 1, Fig. 2(A), shown previously, represents the case of a department store installation with cold cathode fluorescent and incandescent lighting. There were several single-phase induction motors with associated capacitors. Now, it is suggested that the reader answer the question: If opening of any part of the load in customer selling hours is objectionable, how many operators would accept the Fig. 2(A) phasor diagram as proof of proper connections? The operator in the actual case had reason to suspect fluorescent lighting and capacitors. He returned after normal work hours and made a test with only incandescent lamps as a load. This led to discovery that *A* current transformer had been installed with reverse polarity in *B* conductor; see Fig. 2(B). Fig. 2(C) represents correct connections.

Observe that the phasor diagrams for both the wrong and right connections (Figs. 2(A) and (C) respectively) give correct energy registration, or 150 watts. However, a light load is depicted and an increase in loading will cause the as-found listing in Fig. 2(A) connections to cause under-registration. Tests under light load conditions where fluorescent lighting or capacitors are a major part of the loading should be suspect.

Examples 2 and 3 have been discussed. Example 4 represents load-comprised induction motors, capacitors, and incandescent lighting. Fig. 5(A) is the phasor diagram at the meter test switch. The reader may decide as to the correct connections. This case demonstrates a hazard to any audit. As-found connections are shown in Fig. 5(B).

An example similar to this was described in the NELA article.[1] All current transformers were connected to wrong meter current coils and with wrong polarity. Fig. 5(C) represents correct connections.

A competent operator probably would suspect that the estimated load did not match the power factor of the meter test switch phasors. The average operator would probably approve diagram Fig. 5(A). However, for even the most competent meterman there is lack of the positive evidence desired. Tracing of connections should be made in addition to the Woodson check. Unbelievable as it may seem, 2 of the 13 errors uncovered were installations with this type of wrong connection. Observe that this is a balanced 3-phase load. Consequently, this type of fault can occur on any 3-phase delta system as well as on a 3-phase 3-wire Y. Since the error is located in the connections and not in the meter, it is expected that the operator will accept the 165-watt measurement as being satisfactory.

Example 5 covers an intercompany-tie metering installation in rural territory at a location without any instrumentation to determine the nature of the load power factor. Single-phase farm load and single-phase capacitors were evident. Energy could flow from both ends of the line. Would Fig. 6(A) be accepted as representative of the load and proof of proper connections? The reader may wish to decide. After Fig. 6(A) was determined, it was requested that one generating station have its excitation increase. The component change in current at the test location was thus known to be leading and a repeat test gave more evidence that the as-found diagram was correct. In this case, because of the demand for more integrity of decision, all visible connections were checked. As the diagram appears reasonable, Fig. 6(B) representing a wrong connection, is included to show how easily it could be approved. Although the error of the Fig. 6(B) case is only the difference between 175 and 170 secondary watts, any increase in load will probably cause more lagging current and a percentage decrease in amount of proper registration.

Example 6 (Fig. 7) shows the superiority of a "Woodson" over a meter stator check. The load was incandescent lighting, induction motors, and no capacitance. A meter stator tester may attribute "backward" rotation of stator *A* to low power factor. Observe, also that a meter installer may reverse I_a leading to an improperly verified installation. The phasor diagram showed an obvious error. A ground was found on the secondary wiring of the current transformers. Inspec-

tion shows that I_b was advanced in phase position by the fault, and I_a retarded. If the ground fault had been at another location these effects might have been reversed with the result that the meter disk would show "forward" rotation for each individual stator. Hence, in this assumed version, if tests for grounds were not made there would be no significant clue to signal either meter stator or Woodson tester.

Example 7 shows an unbalanced induction motor and incandescent lamp load, again included to show the superiority of a Woodson over a meter stator test. Assume that reliance for verification was placed upon a stator check to determine correctness of transformer connections. Then, in the as-found phasor diagram, both stators will run forward, indicating a reasonable proof of proper wiring. On the other hand, trouble is clearly indicated by the three current phasors determined with the kit. As-found I_c of Fig. 8(A) and (B) was reversed and is corrected in as-left listings in (C) and (D). This unbalanced load with low power factor and the loads of examples 4 and 9 are exceptions in that fullload registration is greater with incorrect connections.

Example 8, in Fig. 9(A), is the result of a 3-stator Woodson test of a 4-wire Y load of incandescent lighting. The reader may decide as to the proper connections.

This is a definite hazard case. I_b is actually I_n as the current transformer is in the neutral. I_n and I_b are identical. Observe that both I_b and I_n are required to balance the vector sum of I_a and I_c. How many metermen using a Woodson kit or making a meter stator investigation would uncover this error? An alert Woodson operator realizes the danger of a possible misplaced current transformer, especially when inspection shows that the neutral current approximates a phase current, and as a consequence he performs the indicated additional checking. Although there is no registration error at the condition shown, normally with a more balanced load the meter would measure only partial energy consumption. Again, the watt table verticals add to zero, although theoretically they should not. This is because measurement was not sufficiently accurate to show the difference caused by the small neutral-to-ground voltage. The frequency with which a neutral current approaches a phase current in magnitude and position is surprisingly high, indicating that the possibility of a misplaced current transformer cannot be ignored. Examples 4 and 8 constitute two types of fault where the kit data may give very plausible "proper" phasor diagrams even when load phasors are known precisely.

In example 9, the service supplied a typical small machine shop load, comprising a number of single-phase motors and two 3-phase motors, the latter each driving a d-c generator used for welding. There were no capacitors. The two through-type current transformers were pole-top mounted. The Fig. 10(A) diagram would undoubtedly be accepted by most testers. The actual tester questioned the phasor unbalance and measured the service conductor currents with his clip-on ammeter. The values obtained did not agree with the meter test switch phasors. One current transformer, as shown by Fig. 10(B), was found connected in the closed delta of the power transformer low-voltage connections rather than in the service conductor. There was a possibility in this case that a careful visual check of connections from the ground might have disclosed the fault. Hidden in some cubicle, such a wrong connection would probably defy detection. This load had a very low power factor and caused the true energy to be less than the as-found metered quantity. Figs. 10(C) and (D) show correct connections.

In Table I eight of the examples just described involving wrong transformer connections were subjected to several of the more popular tests. Opening-line or primary wires was not included as it is no longer considered practical. The Kouwenhoven check requires a nearly balanced load or the test becomes complicated for 3-wire cases. It is not applicable to four wires. The Ackerman and opening voltage leads checks failed almost completely.

Meter Checks

Internal meter connection faults have not been adequately discussed. Examination of modern polyphase watt-hour and watt-hour demand meters shows that internal terminal reversal of potential coils is possible. Grounds are possible. Current coil reversal is not probable. Coil

‖ Yes, but only under conditions described in text.

interchange does not seem possible. For graphic meters both coil reversal and interchange are possible. As with the instrument transformers, the possibility of faults in meters combined with tests made with relatively small currents in one phase, capacitor power factor or voltage control and 4-wire services have made meter stator tests, using the customer's load, more vulnerable to error.

In the 5,000 cases covered by this report only one internal meter-wiring fault was discovered: a reversed potential coil in a graphic meter. However, if the ground of example 6 (Fig. 7) had occurred in the meter after installation, instead of on the transformer secondary, probably no usual meter test with customer load would show the fault. A transformer burden test, used in many companies, probably would uncover the defect. The diagram, from data taken at the meter switch, would normally show the incorrect as-found phasors. However, this assumes that the transformer ground is on the commoned side of the current coils. Nonstandard meter test switch wiring (which does occur) might cause an as-left version of the diagram and result in improper verification. If a reversed meter coil is substituted for the reversed transformer leads of example 7, the diagram will show the as-left arrangement rather than the trouble indicated by the as-found relation. Only the registration discrepancy of 155 Woodson watts against 270 customer-meter watts would give a clue to the error. Another load condition might decrease this difference sufficiently to afford no clue.

If it is conceded that very infrequently the internal wiring of a meter may be misconnected, the best "field" defense would seem to be a check for grounds plus a calibration test using a phantom load and a portable watt-hour meter standard.

One fault discovered by the burden test was a carbonized path between the three current terminals on the back of a meter test switch. Accuracy of the meter was not affected significantly at the time but more humid conditions might well have caused low registration.

For the period of ten years during which tests of 5,000 installations uncovered the 13 wrong transformer connections described, 13 billing constants were also found to be in error by reason of the verification checks disclosing wrong multiplying constants.

SUMMARY OF FIELD FINDINGS

The examples described herein incorporate the limitations of Woodson or other procedures and are included to demonstrate how wrongly connected meters can be "verified." Eight of the 13 incorrectly connected meters were found obviously wrong by casual inspection of the phasor diagram. Diagrams of examples 6 and 7 fall in this category although, as explained before, meter stator tests would probably not uncover the errors. The cases that demand serious consideration are those similar to examples 1, 4, 5, 8, and 9 where routine of "correct" installations is likely to dull the alertness of the operator.

Some advocates of the Woodson procedure consider that only limited competence is needed in field testing. These advocates consider that the responsibility for decision of phasor-diagram accuracy should rest with a test-reviewing engineer. They have a strong argument for all but a few per cent of installations. These few, however, interspersed among a large number of routine cases require a high order of competence for recognition of their special status. Thus, matching the phasor diagram taken at a meter switch against a tie-line load, or a complex-motor fluorescent-light capacitance load, requires engineering ability. No reviewing engineer at a desk can make up for lack of talent at the test site where observations and ability are needed to detect clues denoting a wrong connection. Sometimes, and perhaps for good reason, installations are not "standard" or present particular difficulties. Relays and other nonmetering devices connected to instrument transformers may forbid the opening of circuits. Meter-type application may be questionable. Local requirements and/or other demands of policy may make problems for the tester. Wiring or mountings may be inferior. This requires operators preferably with wide experience, sound judgment, tactful personalities, and dedication to maintenance of accurate metering.

Field operations using the Woodson method are considered economically justified in comparison with costs of other methods of proving connections. In the author's company the operator is furnished with an automobile, a kit weighing 36 pounds, associated tool and lead box weighing 23 pounds, an 8-pound register gear ratio checking device, a clip-on ammeter, and a telescope for reading pole-mounted transformer nomenclature. The 5,000 installations were checked in the past ten years at a rate of over four per day. The operation included travel from a centralized location, the auditing of complex totalizing installations, check of meter constants and transformer accuracy

Vol.
Pt. 1
1959

records, and report writing, as well as the Woodson check of connections. Time at a metering location for over 95% of the installations average about 45 minutes. Recently a kva metering test has been added to the tester's responsibilities. The operator, at the installation, quickly completes the meter test switch phasor diagrams as well as making decisions on connections as being correct, incorrect, or inconclusive. An independent engineer makes a review of diagrams at headquarters. This engineer has made no reversal of a tester's judgment of correct or incorrect connections. Geographically operations cover four states and a local meterman accompanies the operator to show the latter the locations to be checked. In turn the meterman receives instructions in this phase of metering.

The author has tried to show the merit of present systems, as shown in the following summary.

1. *Visual Tracing of Connections:* This method requires a minimum of equipment and technical competence. It is subject to such handicaps as pole-mounted transformers requiring the use of ladders, or linemen as checkers working with a meterman on the ground, transformer connections in conduit where splices of differently identified conductors are possible, fading and discoloration of conductor insulation identification, color blindness of tracers, mechanical tracing errors, inability to discover short circuits and grounds, physical hazards, and wrong nomenclatures. The human element is judged unequal to the task of approaching the required order of effectiveness where this procedure is used. The visual tracing of connections is generally supplemented with item 2.

2. *Meter Stator Tests:* A check of Table I shows that meter stator tests using the customer's load are deficient in the selected examples. Knowlton presents a comprehensive table of 3-wire 3-phase service limitations.[4] Any method which does not determine approximate magnitude and phase relationship of phasors is certain to fail too often. The meter stator test procedure is sometimes used as the sole means of verifying transformer and meter switch connections.

3. *Woodson Method:* Originally, in 1928, with only 3-wire services and ability to limit loads to balanced 3-phase known impedances, the procedure was almost foolproof. Since this procedure incorporates item 2 and, in doubtful cases, may occasionally use item 1, it readily merits top rank for integrity. However, today, the 3-stator kit for proving 4-wire services is not adequate, and the required determination of load phasors occasionally exceeds the capabilities of testers.

4. *Meter Calibration and Ground Faults:* This is a procedure which supplements any of the foregoing three examinations with burden and/or ground tests and a calibration test using a phantom load and portable watt-hour meter standard which will eliminate any significant errors in the meter or its connections to the meter test switch.

NEW PROCEDURES AND TEST DEVICES

Assuming the soundness of the preceding summary of findings, the problem facing the industry is to gain a higher order of integrity in proving meter connections. This paper does not provide a complete answer.

An ideal method for verifying instrument transformer connections to a meter would compare load phasors with meter phasors. To be practical the method must be safe, reasonably economical of time, it must avoid interruption of service to the customer, and provide complete integrity within the capabilities of metermen. The author's company has made partial attack on the problem by: increasing the competence of Woodson testers, using the 3½-stator Woodson kit on 4-wire Y services and, where practical, making magnitude measurement of service conductor currents with a clip-on ammeter.

Increasing the competence of Woodson testers is probably most easily accomplished by having the verification function performed by a few selected and trained specialists. This normally means centralization of the entailed work where a company operates over a large area.

The 3½-stator Woodson kit has been used by the author's company for 4 years. In many cases the fourth current it determined gave desired security. By means of this fourth current the table data can be checked horizontally and the phasor currents on the diagram can be added to zero. This proves that most of the data are consistent, a required step in the procedure.

Other means of adding to the integrity of checking have been tried. The recently introduced 15-75-150-750-ampere hook-on, transformer-coupled ammeter insulated for 8.7 kv to ground is a useful tool to measure load-phase currents when such a check is demanded and where conductors are accessible. This permits a magnitude comparison of meter switch phasors with service conductor currents. This instrument was also used in an experimental test to match load phasors against meter switch phasors by means of a cathode-ray oscillograph and an electronic switch. The corresponding meter switch and load phase wires were readily paired by observing simultaneously different combinations of a load current and a meter switch current. This resulted because the screen normally showed two waves either in phase or nearly 120 degrees out of phase. Phase sequence of the load was established by noting the left-to-right order of two load phase currents on the screen. Subsequently, the meter switch potentials were paired with the potential-transformer primary currents obtained with the hook-on ammeter. This required knowledge of the power factor of the input to the potential transformer and had the disadvantage of working with high harmonic content from the hook-on ammeter. Nevertheless, reasonable proof of connections was considered to be obtained since, by visual inspection, current and potential transformer primary connections were correct, and it followed that correspondingly paired meter switch currents and potentials must also be correct.

This method avoided the opening of any connection except at the meter switch. This is desirable as disconnecting wiring during tests presents the hazard of wrong reconnection. However, if the secondary terminals of the potential transformers are opened, an oscilloscope indication is obtained free of harmonic content and phase displacement, making pairing of waveforms a much simpler task. The proper working combination or pairing of voltages and currents could also be checked by opening a specific potential transformer at the secondary terminals and determining if the corresponding potential has disappeared at the meter switch. With sufficient output from the clip-on instrument, phasor-diagram data of the primary system could be obtained and the resulting diagram oriented and compared with the diagram at the meter switch.

The practicability of direct sensing of load phasors as described depends upon physical accessibility to the primary system. For this reason a large proportion of installations will not yield to this solution. Better sensing devices for current in, and voltages on, the primary conductors would also make the test more practical. The electronic wattmeter in combination with a workable Hall effect sensing device might possibily furnish an answer. Again, because the original Woodson test is faster and more convenient, the extended method just described is considered to have practical merit only where the normal procedure has failed to give conclusive proof of connections.

Rudd in 1936 proposed using Lissajous figures obtained from a cathode-ray oscillograph to construct a diagram of phasors at the meter switch.[5] Actually the publication title is limited to current transformer connections, and only an ammeter was used in addition to the cathode-ray oscillograph. There appears to be no reason why potential transformer connections could not be included. Essentially, the proposal substitutes the oscillograph for components in the Woodson kit, but the results obtained cannot have the exactitutde of the volt-ampere-wattmeter procedure nor does it provide easily recorded data for engineering review. Neither does it incorporate all the self-checking features used to prove integrity of the Woodson data and diagrams. The same knowledge of load phasors is required as with the Woodson method.

The Woodson operator could readily make acceptable separate stator registration tests of the meter with his kit equipment and the addition of a suitable resistor to obtain a known current coil loading. This would avoid errors caused by using an inadequately known customer load. The resistor would be inserted in potential supplies to obtain the test current. For example, potential AB could thereby furnish current for the corresponding current coil A where voltage AB and current A constitute torque requirements for a meter stator. This assumes that meter test switches are installed and a Woodson check is desired before the first customer billing. As yet in the author's company this test has not been made part of connection verification procedure.

Conclusions

1. Experience indicates that over 99% of connections in instrument-transformered metering are originally installed correctly. Of the errors made, the percentage detected by a connection verification test will depend upon the type of wrong connection, the load, the test procedure, and the abilities of testers. Thirteen wrong connections in a check of 5,000 installations were found on the author's system. The embarrassing question presented is, "How many were not found?"

2. A basic difficulty lies in the fact that the test load for proving transformer connections must be the customer load, a quantity which cannot always have its phasors adequately known. This feature of unknown load phasors has increased in the past 25 years because dissymmetrical voltage services, leading power factor and unbalanced loads, and occasions where a tester has been unable to command a simple test load, have all become more numerous. Consequently, the possibility of verifying an incorrect connection has increased. A survey of technical publications shows an absence of proposals to modernize 1928 practices to counter this added vulnerability.

3. Stator and other popular meter tests made at the meter test switch, using the customer's load, are insufficient to give required security either against faults in the meter or in connections to instrument transformers.

4. The Woodson method for finding faults in transformer connections to the meter test switch is considered superior to other procedures. With highly competent operators most errors in connections will be discovered.

5. Separate and combined stator calibration tests made at the meter test switch, using a phantom load and portable rotating standard with addition of a test for grounds will give practically foolproof indication of faults in the meter.

6. A better method of connection checking is a need, and should be a challenge, to the industry. As an example, one procedure would compare oscillographs of load phasors with meter test switch phasors. To be practical, a connection verification method must be safe to personnel and reasonably economical of time; it must avoid interruption of service to customers, and provide complete integrity of action.

Discussion

Thomas D. Barnes (Westinghouse Electric Corporation, Raleigh, N. C.): The author has done the industry a valuable service in his comprehensive paper. In complicated meter testing such as for connection verification, it is as important to know the limitations of a test method as it is to know the procedure.

The many variables entering into present meter installations such as dissymmetrical voltage services, leading load power factors, and unbalanced loads may well set up situations wherein the only characteristic that can be considered definitive is Blondel's theorem. The author shows, in Table I, the unresolved checks of the various test procedures currently used, and illustrates that no one method can give an unequivocal answer.

An important point is the advisability of employing highly competent technicians for checking out meter installations for integrity of connections. To the test results must be added the ability to trace connections quickly. Figs. 4, 7, and 8 are examples where connection and polarity tracing was either necessary or advisable to confirm the correctness of connections.

The recently introduced single-stator network meter is an example where another variable must be checked; that of phase sequence. Heretofore, phase sequence has been of importance only in var-hour metering.

Unfortunately for the meter tester, phase sequence of polyphase circuits are not standardized in the states as they are in Australia, for example, where all line conductors are coded by red, yellow, and blue markings.

The author mentions the need for some method of checking for proper connections of all installations. There may be a practical way but the need of establishing both the load phasors and meter test phasors without interruption of service makes the problem extremely complex. In the meanwhile, the author clarifies the proper use of available methods.

D. M. Smith (General Electric Company, Somerworth, N. H.): The paper is a timely and comprehensive yet understandable treatise on a complex and difficult subject. It shows that today's changing load pattern has markedly increased the hazard that substantial revenue may be lost by approval of incorrect meter connections. It is indeed fortunate that the total probability of such errors on a percentage basis is still very small.

In view of the difficulty of proving with complete assurance that the connections of an installation involving transformers are correct, it is highly desirable that the chances of incorrect wiring during installation be reduced to the absolute minimum, by adhering to standard connections wherever possible, among other factors. In general, the utilities are consequently highly reluctant, and rightly so, to adopt a metering scheme which involves nonstandard connections of instrument transformers.

To extend this principle a step further, it might well be used as an argument in favor of adopting the class *200* self-contained polyphase meter for 200-ampere services, in preference to the use of current transformers at this level, thereby reducing the hazard of incorrect connections. Such is already the practice of many utilities, although not necessarily for this reason.

This author makes an excellent case for the use of the Woodson method as the one best test, whether or not auxiliary tests are made, and it is to the credit of the orginator that, 30 years later, a better method has not been devised. It would be of interest to

Vol.
Pt.
195

know, in this connection, what percentage of utilities use this method, and what their experience has been in uncovering cases where the Woodson diagram was capable of misinterpretation by the average user.

The author mentions the use of a portable watt-hour meter standard for proving accuracy and integrity of meter and connections to the switch, together with use of a clip-on ammeter where practical, to check primary currents. At least one utility has taken a further step by using a polyphase portable meter standard in conjunction with clip-on current transformers, to get closer to customer's load. This of course is subject to limitations in accessibility of primary leads.

Since this paper highlights so successfully the shortcomings of the best-known methods of proving metering installation integrity, it is unfortunate that a better solution to the problem cannot simultaneously be proposed. It is to be hoped that this paper will focus attention on the need for further improvement in methods.

F. W. Warburton: Mr. Barnes and Mr. Smith are thanked for their comments. Their statements describe the problem with enhanced clarity. However, a possible misunderstanding concerning the need of phase sequence may result from Mr. Barnes' discussion. It is answered by the facts that the establishment of phase sequence is a component of the Woodson procedure and phase sequence indiction is part of the Woodson phasor diagram.

There was an absence of discussion from utility metermen. As reported in the paper there has also been an absence, during the past 25 years, of publications describing any serious attempt to modernize proving of polyphase metering connections. It appears that either the industry has neglected the subject or that the author is overconcerned.

Statistical Approaches to Selecting Domestic Meters for Test

LARRY DWON
MEMBER AIEE

J. A. MORRIS
NONMEMBER AIEE

THE AMERICAN ELECTRIC Power Company (AEP) system is an integrated and interconnected electric power network, including six principal operating companies serving parts of seven states: Michigan, Indiana, Ohio, West Virginia, Virginia, Kentucky, and Tennessee. The majority of its revenue watt-hour (whr) meters are selected for test on the basis of geographic areas, each of which include one-eighth of the meters in an operating company. Each year all meters in the geographic area are tested, with some minor exceptions, so that over a period of 8 years all meters on the system are tested once.

Meters are tested to assure accurate energy measurement. This is not only the company's responsibility, but also the concern of state public utility commissions. While the code for electricity meters[1] recommends that single-phase meters of 12-kva rating or less, which includes most domestic service whr meters, be tested at least once every 96 months, not all state commissions conform to this recommendation.

Past test results reveal that for every 100 meters tested, only four are found to be inaccurate beyond the prescribed limits. This very inefficient method of finding the meters needing attention, and the prospect that meter-testing expenses will continue to increase, motivated the reexamination of the present method of selecting whr meters for test. Because meters have been improved over the years, it was anticipated that those subject to more frequent error may be concentrated in some earlier classes. If this could be proved, then meter testing could be concentrated on those classes, and the number needing a test would be much smaller than at present.

Over the years, manufacturers have made improvements in the insulation and magnetic materials so that modern whr meters retain their calibration over much longer periods than those built previous to 1940, when stable braking magnets were introduced. Since all four meter manufacturers in this country made similar or equal changes at approximately the same time, such progressive changes now may be considered as establishing five age groups or categories, covering the period from 1910 to the present. This segregation is demonstrated in Fig. 1. Because of such improvements, present procedures require the testing of a large number of accurate meters, in order to find the small number that are in error. If selective testing were possible, less meters need be tested each year and, as inherently inaccurate models or types were uncovered, they could be retired if the economics involved justified such action. It was anticipated that a means for testing only a small statistical sample of all meters could be devised which would assure that the whole population were maintained within acceptable tolerances.

Statistical procedures are useful tools, but available literature does not deal with their application to the meter testing problem explicitly enough for easy understanding by people not familiar with statistical methods. This paper, therefore, briefly reviews available facts concerning present methods of testing meters, the more basic concepts of statistical sampling theory, and several procedures which might be applied to the meter testing problem.[2]

The foregoing implies that meters can be divided roughly into five developmental classes and the ability to maintain their accuracy is different for each class. The more modern meters are practically troublefree, as can be demonstrated by actual test data.

Statement of Problem

The meter classes on the AEP system include several types of each of four manufacturers. Types of a given vintage are believed to maintain approximately the same accuracy for any similar service environment. The problem, therefore, is to devise the most economical system of sampling, so that for each class of meter enough of them would be tested to determine with predictable precision and reliability the probable number of all meters of that class, which are within acceptable accuracy limits; and at the same time to assure that the new method is at least as reliable as the one now used and acceptable to the various state commissions. Furthermore, proper evaluation of the test data would show whether or not the test

---

Paper 59-167, recommended by the AIEE Indicating and Integrating Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted October 24, 1958; made available for printing December 17, 1958.

LARRY DWON and J. A. MORRIS are with the American Electric Power Service Corporation, New York, N. Y.

The authors wish to thank C. L. Lucal and R. V. Keich, engineers on the AEP system, for their investigations and data with respect to some factors which influence meter errors. They also wish to thank Floyd Busch, N. P. Demos, and E. Davis of the General Electric Company.

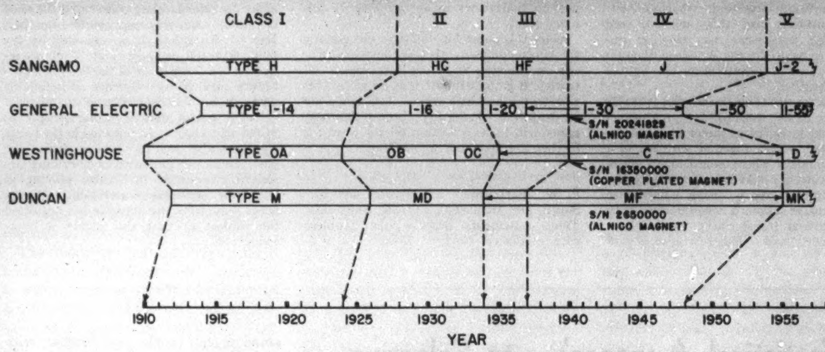

Fig. 1. Years when major domestic meter improvements occurred

data analyzed by class are truly representative of accuracy or whether further analyses by meter type is required.

The present testing method may be considered a 100% sampling of a geographic area which may not be typical of all meters on the system. Therefore, no statistical inference can be made from it about the other meters. Statistical methods may involve many kinds of sampling procedures, but all of them have certain things in common, e.g., they sacrifice accuracy for economy, but in each case the amount of accuracy is predictable. As much accuracy can be attained as one is willing to pay for.

Analyses of Present Records and Procedures

While the methods that are discussed herein apply equally well to all AEP operating companies, the specific example discussed in this paper approximates the situation for one of them. This company maintains records as follows:

1. Each meter has a history card showing the year of purchase, serial number, company meter number, tests, location, etc.
2. Each division of the company maintains these history cards segregated by manufacturer and capacity. Within a given manufacturer's group of meters, however, the various classes of meters and their location, whether urban or rural, are intermingled.
3. The company maintains a symbol book which theoretically lists the meters consecutively as to date of receipt and by various manufacturers.
4. Test slips for each meter are kept in a separate file arranged by meter number.

History cards seem to provide the best available frame of reference, from which samples of the meter universe can be selected. However, at some future time it might be advisable to refile the history cards by homogeneous study groups as shown in Fig. 2.

Meter Classes

Major improvements were made by most manufacturers at about the same time so that Fig. 1 defines approximately the types of meters in use today, segregated by class.

Fig. 3 shows the distribution of meters as follows:

1. Present rate of retirement of class I and II meters.
2. Rate of retirement that might be considered to eliminate class I, II, and III meters by 1965.
3. Rate of growth of class V and all meters on the system.
4. Rate at which class III meters are being converted to essentially the equivalent of class IV type.

Knowledge of improvements made to these meters suggests that those in class I are subject to more frequent errors and need more attention than those in class V, for instance. Special tests conducted in selected urban and rural areas substantiate the suspicion that meter errors are a function of meter class and location, as shown in Table I.

Factors Causing Meter Errors

Meter inaccuracy can be caused by several factors:

1. Age of meter: newer meters are inherently better able to maintain accuracy because they are better designed, have improved materials, and built-in protection against lightning effects.
2. Manufacturer: competition tends to keep all manufacturers' products about equally good based on years of periodic test results. This factor may merit future study, both to stimulate competitive development and improvements and to obtain benefits of the ability of one particular type to maintain accuracy better than any other type.
3. Location: local conditions, such as frequency of power surges, lightning frequency, or corrosive atmosphere, may affect meter accuracy, particularly the earlier meter types.

While other factors may also cause meter errors, the above seem to be most important. The immediate concern of this investigation, however, is the class of meter and whether its location is urban or rural.

Tests Results

The 1956 total meter accuracy for the AEP system is indicated below for the 96-month class of meter:

Distribution of Meters by Error Classes

Error, %	Per Cent Tested Light Load, 10% Rating		Full Load, 100% Rating	
0–1	66.83		86.05	
1–2	21.20	88.03	9.84	95.89
2–5	8.05		1.94	
5–10	1.34		0.44	
10 and over	1.15		0.35	
Stopped	1.43		1.38	
		100.00		100.00

This represents 221,637 meters tested over the entire AEP system.

On the basis of these data, approximately 88% and 96% of the meters tested met acceptable standards for light-load and full-load tests, respectively. Limit-

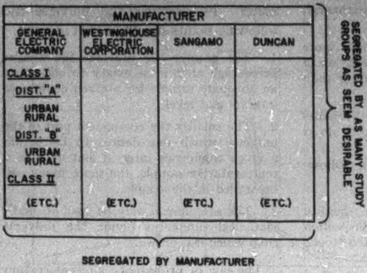

Fig. 2 (left). Meter history card file arranged by possible homogeneous study groups

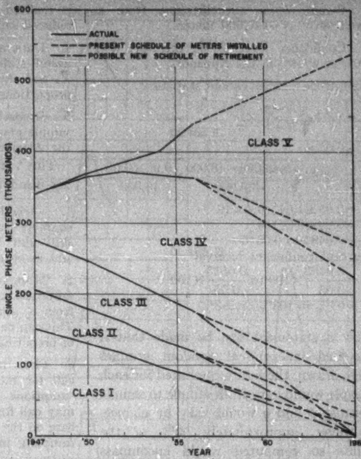

Fig. 3 (right). Meter class distribution

ing this discussion to full-load conditions, it can be said that out of each 100 meters tested, four will be outside the acceptable limits of plus or minus 2% error. It is this inefficient procedure which motivates the application of statistical sampling methods to this problem.

Statistical Samples and Inferences

The purpose of any statistical survey should be the gathering of accurate data about the object of study, i.e., the universe. One hundred per cent accuracy can be obtained only if the entire universe is included in the sample. Most often this is impracticable, very expensive, and unjustifiable.

When the universe needing investigation is relatively large, some savings, at the risk of error, can be realized by using scientific sampling methods. Scientific sampling is a particular way of selecting and investigating a part of a universe in order to find out about the whole universe. Scientific sampling is based on the mathematical theory of probability, and these concepts presuppose a known distribution of items in the universe and a similar distribution in the sample.[3]

If proper methods are used, under applicable conditions, inferences can be made about the entire universe from data obtained in relatively small samples. These inferences will lie within predictable confidence intervals, and at a known confidence level. Proper methods imply a scientific sample, random and representative, and applicable conditions imply a known distribution, preferably normal, of items in the sample and universe.

CONFIDENCE INTERVAL AND LEVEL

The following factors are inherent in the results of any sampling procedure and thus require early definition:

1. Confidence Interval. The range of precision within which the statistic of the sample will probably fall.
2. Confidence Level. The probability that this statistic of the sample will fall within that range.

These two factors are mathematically related in the Appendix. The narrower the range, the less probable that a given sample will fall within the range. This is turn depends upon the type of distribution of items in the sample and universe and the statistic being measured.

The confidence interval is expressed mathematically in equations 1 and 3. The following example may clarify the interpretation of the foregoing terms:

1. Sample items = 48,000 meters actually tested.
2. Proportion with less than ±2% inaccuracy $= p = 0.95$.
3. Proportion with more than ±2% inaccuracy $= q = 1 - p = 0.05$.

4. Sample is a scientific one from a universe of $N=440{,}000$ meters.

5. Confidence level = 90%, therefore $k=1.64$, as shown in the Appendix.

Confidence interval (about statistic q)

$$=q\pm k\sqrt{\frac{N-n_1}{N-1}\times\frac{pq}{n_1}}$$

$$=0.05\pm 1.64\sqrt{\frac{440{,}000-48{,}000}{439{,}999}\times\frac{0.95\times 0.05}{48{,}000}}$$

$$=0.05\pm 1.64\times 9.4\times 10^{-4}$$

$$=0.05\pm 0.00154$$

$$=0.0485 \text{ to } 0.0515$$

Per-cent confidence interval

$$=\frac{0.0485}{0.05}\times 100 \text{ to } \frac{0.0515}{0.05}\times 100$$

$$=97\% \text{ to } 103\% \text{ or } \pm 3\%$$

Now a statement can be made that if repeated independent random samples were drawn, the limits computed for each sample would vary from sample to sample because p and q would vary by chance. However, approximately 90% of the limits so computed would encompass the true proportion q of the universe.

We would make a similar interpretation for other statistics that might be used such as the arithmetic means $\bar{X}_s$ in the Appendix.

STATISTICAL APPROACHES

Two statistical approaches have been used extensively in surveys, quality control, and other work, namely, method of Attributes and method of Variables. The Attributes method provides a means for making a statistical inference from a sample on the basis of the statistics p and q, where

p = proportion of sample meters within test limits
q = proportion of sample meters outside test limits and
$p+q=1$

The method of Variables provides a means for making a statistical inference from a sample on the basis of the statistics $\bar{X}_s$ and $\hat{\sigma}_u$, where

$\bar{X}_s$ = arithmetic mean of sample meter test accuracy
$\hat{\sigma}_u$ = estimate of standard deviation of universe

The Variables method has the following advantages as compared to the Attributes method:[4]

1. For any desired degree of precision and reliability, fewer items are needed in the sample for single sampling procedures.
2. Measurement of a sampling item under the Variables method gives much more information about that item than under the Attributes method.
3. The Variables method will yield more information about the universe than would the Attributes method. This advantage is realized in a practicable way through reduced sample sizes.
4. Data are made available about more useful statistics, namely arithmetic mean $\bar{X}_s$ and standard deviation $\hat{\sigma}_u$ rather than proportions p or q.
5. Borderline items in the Variables sample present no problem, but they do in the Attributes method.

The Variables method has the following disadvantages:

1. Variables inspection of a quality characteristic requires more inspection skill and time, more complicated tools, and in other ways is more costly.
2. More record keeping and more arithmetic are needed after the data are obtained from a sample in the Variables method. This can be minimized by more initial work of preparing graphical charts and tables.
3. Plans based on the Variables method call for more stringent mathematical assumptions. Their selection and installation may call for considerably more ability and care on the part of those administering the sampling inspection program.

As far as the need for more complicated testing facilities mentioned, the disadvantage in not especially pertinent since meters have to be tested. The relative merits appear to favor the Variables method.

UNIVERSE AND ITS DISTRIBUTION

In statistics the universe means all items that comprise the object of study. It is sometimes referred to as the population. In this case it is about 440,000 domestic meters which are being tested on a 96-month cycle. This universe can be limited, if desired to some homogeneous part. For instance, we might want to study only the meters in some district, division, or geographic area. Perhaps we may want only to study one age class or one manufacturer's type of meter. In selecting the universe the following points should be kept in mind:

1. The greater the universe the smaller percentage of it is necessary to constitute an adequate sample for a given confidence interval and level.
2. The smaller the component part of the universe which one desires to be within a given confidence interval and level in a representative sample, the more items will be needed in the sample.
3. The sample can only be used to make statistical inferences about the universe from which it is drawn.

The law of probability suggest certain patterns or distributions into which chance events seem to fall. Chief among these are the Binomial distribution and its approximations, the Poisson distribution, and the Gaussian or Normal distribution. Our problem requires the use of probability concepts, but we will presuppose in our discussion, that if the Attributes method is used, enough items are included in the sample to allow the use of simpler concepts of the Normal distribution. When the sample is large enough, the Normal theory is applicable and these conditions prevail when the following conditions are satisfied:[5]

Observed Proportion p	Sample Size for Normal Theory to Apply
0.4 or 0.6	50
0.3 or 0.7	100
0.2 or 0.8	400
0.1 or 0.9	1,000

Actually our p values are in the order of 0.96 which means that to apply Normal distribution concepts we would penalize ourselves with an unnecessarily large sample. If Normal theory does not apply, charts or tables prepared directly from

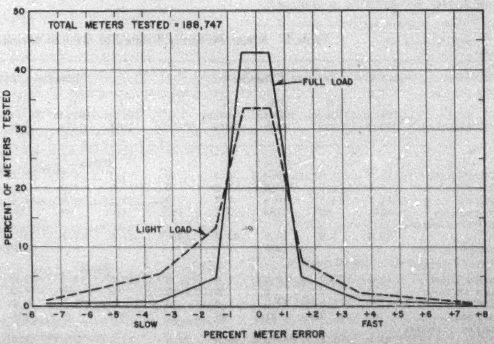

Fig. 4. AEP system meter accuracy frequency distribution, 1956

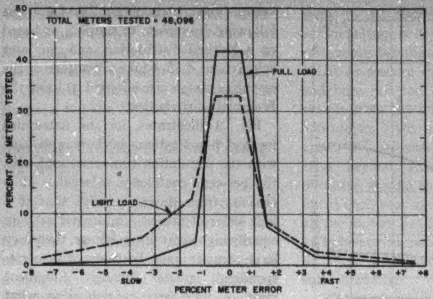

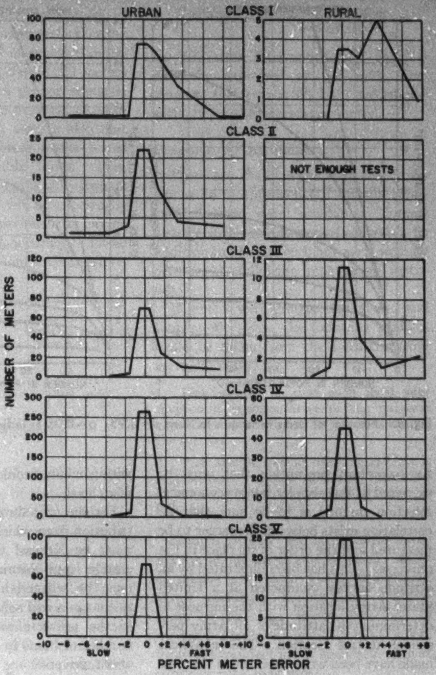

Fig. 5 (above). Subsidiary company system meter accuracy frequency distribution, 1956

Fig. 6 (right). Subsidiary company division meter accuracy frequency distribution, July 1957 tests

the Binomial distribution are available.[6]

When applying the Variables method it is required that the test samples and the universe be Normally distributed. These should be tested by available statistical methods. Therefore, one should obtain a past history of frequency distributions of meter errors early in the application of statistical approach.

In spite of the insistence by some that the Normal universe is not natural or universal, a great many experimental, manufacturing, economic, and other processes do produce distributions that are fairly near Normal. Figs. 4 through 6 illustrate this contention in varying degrees for the following situations:

Fig. 4: AEP system total meter accuracy frequency distribution (full and light load) in 1956.

Fig. 5: Subsidiary company total meter accuracy frequency distribution (full and light load) in 1956.

Fig. 6: Subsidiary company special tests in division 1 on classes I to V meters in rural and urban areas.

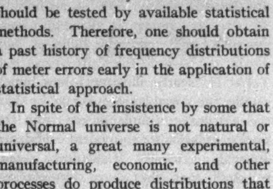

Fig. 7. Area between selected ordinates of normal curve

The Normal distribution is symmetrical and unimodel. Hence, its mean, median, and mode are all the same. The fractions of the Normal universe lie within certain symmetric limits as shown in Fig. 7.

Scientific Sample

A scientific sample is selected at random and has the following characteristics:

1. Each item is drawn independently.
2. Each item has the same probability of being drawn as any other one.
3. The homogeneous items in the sample are proportionately distributed, or representative, in the same manner as in the universe.
4. Such a composite of items reflects the universe from which it was drawn, within a predictable error of estimate and a known confidence level.

A truly random sample is sometimes difficult to obtain because the frame of items in the universe may not be available or is in such a form as to make it impracticable to use properly. The simplest way to visualized the selection of a random sample is to use a drum in which the universe is represented by consecutively numbered small marbles. The container contents are continuously mixed and items are withdrawn blindly one at a time. This procedure is obviously cumbersome.

One method, called "simple random" selection, which accomplishes the objective with more finesse, is to utilize random number tables. Each element in the universe is assigned a number. These numbers may be the place order of meter history cards. Successive numbers of the appropriate size are read from the table, repeated numbers being discarded, until the required sample size is attained. The elements of the universe with corresponding numbers constitute the sample.

Another method, called "systematic random" selection, can be used when applicable. In this case one enters the random number table to select blindly a single numbr which falls within the group of numbers of the universe. Then every ith number is chosen as part of the sample where i equals the following:

$$i = \frac{\text{Items in universe}}{\text{Items in sample}}$$

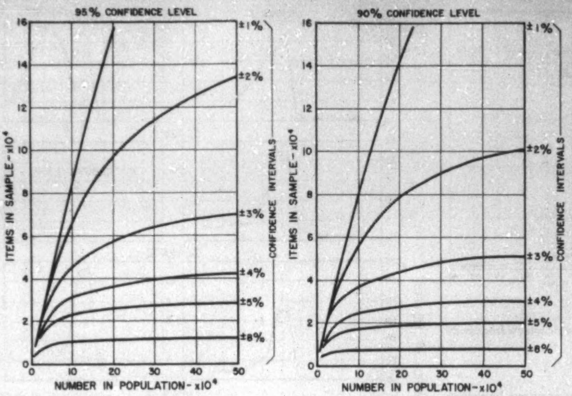

Fig. 8. Number of items in sample for case $p=0.95$, $q=0.05$ at indicated confidence levels

An important precaution that must be exercised in this simpler, more economical selection method is to be sure that no correlation exists between the factor to be measured and the order of its place in the universe. This has been illustrated by an attitude survey conducted at a United States Army location with the purpose of determining the attitude of all Army personnel at this location. The inferences made have been wrong because in this case every *i*th item of the universe happened to be mostly sergeants. The sample therefore was biased by opinions of sergeants.

STATISTICAL INFERENCE

The process by which, on the basis of a sample, a conclusion is made about the universe from which the sample is taken, is called "inference." A statistical inference is always a conclusion about the value of a statistical measure describing the universe: its mean, standard deviation, proportion, etc.

In this study we will consider inferences about the proportion of domestic meters which exceed ±2% error (method of Attributes). Thus, on the basis of the random sample we will judge what proportion of meters in the universe exceeds ±2% error and within what "confidence interval" and on what "confidence level."

We will also consider inferences about the arithmetic mean $\bar{X}_s$ and estimated standard deviation of the universe $\hat{\sigma}_u$ obtained from the meter accuracy test samples (method of Variables). Thus on the basis of the random sample we will judge the arithmetic mean and standard deviation of the meters in the universe and within what confidence interval and on what level.

For the procedure to be valid, the distribution from which the sample is taken must be Normal or depart only moderately from Normal shape; the sample must be selected in a scientific manner so that in a real sense it is an "offspring" of the universe as a whole; and the number of items in the sample (evidence about universe) are sufficient to make the error of estimate reasonable.

ITEMS IN SAMPLE

The number of items in the sample picked from a normally distributed universe is given by equation 2 and 4. The following discussion, to simplify, is based on a Normal distribution, and our later calculations do not take advantage of the saving in sample size afforded by using the Binomial distribution.

Fig. 8 illustrates, for the Attributes method, how the items in the sample vary with the population (universe) and with the per-cent confidence intervals. It is obvious from these diagrams that if a high order of precision is desired with an equally high order of confidence, then very large samples must be taken with correspondingly greater expense. Judgment must be used here to determine what limits to select and with what confidence to be satisfied. These will be rationalized in a following discussion.

Typical values of $\hat{\sigma}_u^2$ and corresponding values of pq from the same sampling distribution are compared in Table II. These values were calculated from test results shown in Figs. 4 and 6.

Table II shows the ratio of n_2/n_1 for the different combinations of $\hat{\sigma}_u^2$ and pq values already mentioned. This ratio was calculated by the following equation derived from equations 2 and 4 where the symbols are defined:

$$\frac{n_2}{n_1}=\frac{\hat{\sigma}u^2}{pq}\times\left(\frac{w^2(N-1)+k^2pq}{w^2(N-1)+k^2\hat{\sigma}_u^2}\right)$$

Table II clearly illustrates how much smaller the Variables sample may be than the Attributes sample picked from the same population for equivalent confidence intervals and levels. It should be noted, however, that the above formula exaggerates the n_2/n_1 ratio because the best

Table II. Ratio of Variable to Attribute Sample Sizes for Equal Confidence Level and Interval and Universe

		Variances (Multiply by 0.0001)					
		Variables, $(\sigma\mu)^2$		Attributes, pq		n_2/n_1*	
Meter Class	Operating Division	Urban	Rural	Urban	Rural	Urban	Rural
I	1	5.25	5.04	1275	2440	0.006	0.004
	2	2.38	5.75	471	1745	0.006	0.004
	3	3.03	7.29	462	2170	0.008	0.006
II	1	7.64		1240		0.009	
	2	1.84	8.49	414	1730	0.005	0.008
	3	3.81	6.03	579	1875	0.008	0.005
III	1	4.94	6.08	975	1120	0.007	0.008
	2	2.76	7.05	430	1640	0.007	0.007
	3	1.68	6.68	162	2224	0.011	0.006
IV	1	0.79		69		0.011	
	2		1.85		204		0.010
	3	1.06	2.10	75	274	0.015	0.009
All	AEP	2.19		394		0.007	
All	Subsidiary companies	2.74		357		0.009	

* These values were calculated with the following conditions:
$N=50{,}001$
$w=0.08q=0.08\times0.05=0.004$
$k=1.64$ (90% confidence level)
Range of $n_2/n_1=0.004-0.015$
Average of $n_2/n_1=0.008$

Attributes sample is not utilized, as explained previously. To design the best Attributes plan the concepts used in quality control, the control charts, should be utilized. These are based on the Binomial not the Normal distributions.[7,8]

Applying Statistics to Meter Testing Problem

We will assume that the universe and samples drawn from it are Normally distributed. To increase this possibility under the Attributes method, no sample of a subgroup in which we are interested will contain less than 1,000 items unless it is physically impossible to do so. Under the Variables method no sample of a subgroup will contain less than 30 items.

While we have no experience to say what is a reasonable confidence interval and level, it might be possible to make an estimate from various aspects of our present procedures. Present practice obtains almost a 90% sample, approximately 48,000 meters out of 55,000 (1/8 of 440,000), from a geographic area and we actually realize almost a zero confidence interval on a 100% confidence level because practically all meters are tested in that specific universe. Those meters that exceed the limit of error are recalibrated or replaced.

However, we cannot make any statistical inference about the meters in other geographic areas until their test period arrives once each 8 years. Practical judgment leads us to believe that the more recently tested meters will have a smaller percentage in error than those which have not been tested for 7 years, for instance. This means that, at the end of a year, approximately 5,500 meters would be expected to remain in error over the system as follows:

Meters	Meters Assumed in Error of 55,000 Each Year: Estimated %	Meters Assumed in Error of 55,000 Each Year: Meters
Recently tested	0	0
Years without test		
7	4	2,200
6	3	1,650
5	2	1,100
4	1	550
3	0	0
2	0	0
1	0	0
Total		5,500

These 5,500 meters may be assumed in error on the system plus some unknown quantity, possibly 4% of 7,000 meters (55,000 to 48,000), which were not tested in the geographic area. This would seem to be inadequate confidence in our knowledge of how many meters on the system are beyond the inaccuracy limits.

Let us assume that the 48,000 meters had been selected as a proper scientific sample from the whole universe of 440,000 meters. We must assume also that about 2% of the meters might be in error beyond acceptable limits. This, of course, is what the sample will estimate for us each year and it will be affected by all the factors listed previously as having an influence on meter inaccuracy. Based on these assumptions our calculated results would be:

Per-Cent Confidence: Level	Per-Cent Confidence: Interval	Probable Range of Meters in Error
99	±4.7	8,800† ±413
95	±3.5	8,800 ±308
90	±3.0*	8,800 ±264

* See previous illustrative computation.
† 0.02×440,000 = 8,800.

Thus with present procedures we estimated a possible range of meters in error of 5,780 (5,500+0.04×7,000) which is many times the ranges computed above. Furthermore, however, we do not have now any idea of how confident we can be that the meters beyond ±2% inaccuracy equal zero plus or minus 2,890 (5,780/2). Under sample testing we are able to compute the probable range of meters in error and what the probability is that this range encompasses the true number of meters in the universe which exceed the prescribed accuracy limits.

At best we can say that our present method leaves us with a fairly wide range of doubt, 5,780 meters, and with no predictable confidence level. A ±8% interval would have a range of 1,406 meters (8,800×.08×2) at a confidence level of 90%, over 400% better than present practice. We also know that a level of 99% and a narrow interval like ±0.1% are used mostly in cases involving life and death decisions. This is not such a case. In quality control a 95% level is used very often.

The subsequent discussion of the costs involved in various possible statistical approaches will give us additional help to judge what confidence level and interval to use. We may now, however, suggest that a 90% level ±8% interval would seem to be reasonable for this problem as a start and that the interval can probably be increased.

It should be noted that there are two ways of interpreting the confidence interval percentage, ±8%, as follows:

1. Confidence interval $= \bar{X}_s \pm 0.08\,\bar{X}_s$ or $= p \pm 0.08\,p$
2. Confidence interval $= \bar{X}_s \pm 0.08$ or $= p \pm 0.08$

In the latter interpretation $\bar{X}_s$ and p must be expressed as per unit. Our usage of the term ±8% is in accordance with the first interpretation noted.

POSSIBLE APPROACHES

There are many ways that this problem could be approached if suitable reference frames were available. Present history cards provide a practical way. In addition to this method, however, we may consider the following hypothetical methods.

If meters were grouped by classes and local subdivisions, the following samples could be taken from the total company meter universe:

1. Pick sample so that each local subdivision is representative of the universe regardless of which meter class falls into the district.
2. Pick sample so that each meter class is representative of the universe, regardless of which district or geographic area it falls into.

Sample 1 would yield some useful information about variations between classes of meters and more useful information about variations among local subdivisions or, in other words, locations of meters. The latter would tell us where local factors affect meter accuracy, such as urban or rural exposure.

Sample 2 would provide a means of making an inference about all meters in the system universe and about individual classes as well. If we assume that our

Table III. Number of Meters in Hypothetical Samples

Attribute Method: Obtained From All Domestic Meters in a Universe of 440,000

Class of Meter	Number of Meters: Class	Samples: A	Samples: B	Samples: C
I	83,750	1,275	2,970	7,350
II	33,750	1,000*	1,400	6,500
III	57,500	1,000*	2,270	7,100
IV	187,500	3,230	7,500‡	7,500
V	77,500	1,425	3,320	7,300
Total	440,000	7,930 †	17,460	35,750§

Case A: Sample selected so confidence (90%; ±8%) applies to whole universe only.
Case B: Sample selected so confidence (90%; ±8%) applies to class IV only.
Case C: Sample selected so confidence (90%; ±8%) applies to all classes equally well.
* Minimum number for normal distribution to apply.
† Only 7,500 items would be required if foregoing condition were disregarded.
‡ Only class IV meets confidence; all others are poorer.
§ Not a representative sample of the whole universe.

Table IV. Number of Meters in Practical Samples

Attribute Method: Obtained from All Domestic Meters in a Universe of 440,000

Division Name	Number of Meters			
		Samples		
	Division	D	E	F
Southern	146,500	2,490	7,000*	7,000
Western	117,000	2,000	5,610	7,000
Central	111,200	1,910	5,350	7,000
Eastern	65,300	1,100	3,120	6,900
Total	440,000	7,500	21,080	27,900†

Case D: Sample selected so confidence (90%; ±8%) applies to whole universe only.
Case E: Sample selected so confidence (90%; ±8%) applies to southern division only.
Case F: Sample selected so confidence (90%; ±8%) applies to all divisions equally well.
* Only southern division sample meets confidence; all others are poorer.
† Not a representative sample of the whole universe.

confidence applies only to the system as a whole, then the result would be case A, the smallest sample for the conditions. For any individual class however, our confidence would be less but still a predictable one. If we desire inferences about the largest individual class to be at the established confidence level, case B, a larger number would be required in the sample; the confidence level for the whole group would be greater, and the inferences about the smaller classes would be on lower confidence levels but still predictable ones. If on the other hand we desire the smallest class to have the reliability and precision, then inferences about all other classes including the universe would have a higher reliability and precision and this would require a very much larger sample. This case is disregarded because it is impracticable.

We might be interested in another situation, case C, as shown in Table III, in which a sample would be selected that is not proportionately representative of the universe, but which does insure each class inference to have the same precision and reliability.

Practical Approach

This company's meter history card file intermingles classes and locations within each manufacturer's group. Since we are not interested at this time in determining differences among manufacturer's products, a systematic sample can be picked from the total company meter universe so that each division is representative in the sample.

The meter classes and their locations are assumed to be intermingled in a random manner. It is reasonable to expect therefore, that a sampling distribution would have the same proportion of meter classes as the system. It is also possible that the sampling distribution would have the same proportion of urban and rural meters as the system. This, of course, should be checked when samples are drawn because concentrated rural programs may have caused meter history cards to be grouped in a manner other than random.

The sample items necessary to satisfy Attributes sampling cases A through C are given in Table III. In Table IV, similar data are given for cases D through F based on the practical conditions mentioned above. Table V shows the sample items that would be needed under the Variables method for case G, which corresponds essentially to cases A and D, and case H, which corresponds to cases C and F. These data are based on a n_2/n_1 ratio of 0.1 and the requirement that no sample shall be less than 30 in any study group. This condition insures slightly better precision and reliability than would be obtained from equivalent Attributes samples.

Table V. Number of Meters in Practical Samples

Variable Method: Obtained from All Domestic Meters in a Universe of 440,000

Division Name	Number of Meters		
		Samples*	
	Division	G	H
Southern	146,500	67	70
Western	117,000	54	70
Central	111,200	52	70
Eastern	65,300	30	70
Total	440,000	203	280†

Case G: Sample selected so confidence applies to whole universe only.
Case H: Sample selected so confidence applies to all divisions equally well.
* Samples selected on basis of $n_2 = 0.01\ n_1$.
† Not a representative sample of the whole universe.

Cost Comparisons

For this study we assume that it costs approximately $1.49 to test a meter.

Table VI shows the cost necessary to test the number of meters that cases A through H require, as well as the approximate difference in testing cost when compared to the present method. This table compares differences on the 99%, 95%, and 90% confidence levels each with a ±8% confidence interval.

We cannot say that these differences in testing cost really represent immediate savings because no reduction in meter-department expense can be effected until the equipment, personnel, and supervision cost of the meter department is reduced. Actually, it is proposed that initially as many meters be tested as necessary but the tests should concentrate on those meters which tend to develop errors sooner. As meter types are uncovered,

Table VI. Cost Comparison of Several Meter Testing Samples

Estimated Difference of Statistical Sampling Methods Over Present Procedure. All Testing Costs Assumed to be $1.49 Per Meter

† Practical cases using samples illustrated in Table IV, Attribute method.
‡ Procedure costs more than present methods.

by analysis of test data which seem to be inherently subject to frequent error, they can be eliminated gradually through retirement, if testing costs compared to replacement costs are unfavorable; or they may be tested at more frequent intervals than once in 8 years. The procedure that should be followed will necessarily have to be developed by experienced meter engineers.

The company already knows which class of meters is the more inaccurate but these data are based on a very small part of its meter universe. However, it is obvious that while the incorrect meter classes are known, one cannot tell which of the meters in those classes are in error. For instance, if it were assumed that meters in classes IV and V would maintain calibration indefinitely, an unreasonable assumption, the company would still need to test about 175,000 meters, 40% of total, this year to locate approximately 5,600 inaccurate meters, 1.27% of total. This, of course, cannot be done in a single year because with present facilities and personnel, only 12$^1/_2$% are tested per year therefore consideration must be given to the following:

1. The elimination, as it becomes practicable, of those meter classes which contain inherently inaccurate meters.
2. The utilization of different testing cycles for the various classes of meters.

Eventually, as the meter universe becomes composed of classes IV and V meters and perhaps others containing even more accurate types, it may well be that a smaller sample need be tested than at present. At that time, it appears that only between 4,000 and 8,000 meters need be tested, if the Attributes method were used, and perhaps something like 200 to 300 meters if the Variables method were used, to assure a degree of reliability and precision now believed to be reasonable. This is based only on study groups mentioned in this report. At this future time, possibly 1965, an appreciable reduction in testing costs may be expected, and what is more important, the cost will not increase greatly as more domestic meters are added.

Returning to Table VI and the foregoing discussion, it now seems possible to show that a 90% confidence level with a minimum of ±8% confidence interval is more than adequate for our problem at present if the Attributes method is used. Table VII compares the incremental increases in the confidence level and the corresponding decreases in differential costs that occur. Taking class A as an example, Table VII shows that if we increase the confidence level from 90% to 95%, an incremental increase of 5.5%, we would decrease the differential cost by 9%, (a faster rate). If we were inclined to go from 90% to 99% the incremental gain in confidence would be 10%, but with an incremental decrease in differential cost of 27%. Other cases are even more extreme. Is it prudent, therefore, to require the increased reliability for this problem? The authors think that it is not, but this needs to be thoroughly reviewed and discussed so that reasonable and acceptable limits are established consistent with all ramifications of the problem.

Conclusions

The following major conclusions result from this study.

PRESENT METHODS OF TEST

1. Meter-testing expense has been increasing each year and will continue to increase as additional customers are added, unless different procedures are devised.

2. Present selection methods are inefficient. Of each 100 meters tested only 4 are found to be in error.

3. Evidence is available which shows that different classes of meters have different frequency of error. These data presently are limited, localized, and inapplicable for statistical inferences about all meters of a system.

4. Evidence is also available which shows that rural meters show higher frequency of error than urban meters. These data also are limited, localized, and inapplicable for general statistical inferences.

5. Present test procedures tell us exactly how many meters are in error and to what degree in a geographic area only. They tell us nothing about the other 87.5% of the meters on the system, most of which will not be tested for seven years.

STATISTICAL METHODS

1. Statistical sampling methods provide a means for making inferences about a large number of items, like meters, on the basis of relatively small samples. These inferences can be as precise and reliable as one wishes them to be. The precision and reliability is mainly determined by the number of items used in the sample and this, in turn, affects the expense of the survey.

2. By judicious selection of desired precision and reliability, savings can be realized in seeking information about the meters with which we are concerned.

3. Until further information proves otherwise, it is suggested that we use a 90% confidence level and ±8% confidence interval as a minimum degree of reliability and precision respectively. There is a reason to believe that practical considerations might dictate a different precision.

4. The advantages of the Variables method surpass the disadvantages so its use is recommended over the Attributes method. The principal practical advantage is the smaller sample needed for a given precision and reliability. This conclusion is based on single sampling methods only.

APPLICATION OF STATISTICS TO THE SELECTION OF METERS FOR TEST

1. Statistical sampling methods are applicable to this problem; first to obtain information about the relative errors in different study groups (meter classes, location, etc.) and second, to sample from the whole meter universe in an operating company to determine significant changes in meter accuracy from year to year.

2. It is estimated that by utilizing

statistical sampling the number of meters needing test on a system with 440,000 meters might be reduced from 48,000 to about 500 some time in the future when and if all inherently inaccurate meters are eliminated. In the interim period a sample of 1,000 meters is suggested to obtain sufficient data about the universe, e.g., the relative accuracy of different classes of meters and how the accuracy is related to location and other factors.

3. If suitable changes are made in the meter department to take advantage of anticipated reduction in testing needs, then considerable savings in testing costs might be realized after all inherently inaccurate domestic meter classes are eliminated. This presupposes that a situation might some day prevail when the average error of the system meters will be so small as to be insignificant. Of course, if a significant change should occur, then testing in addition to the sample will be required which would decrease the savings that would be realized.

Nomenclature

N = number of items in universe

n_1, n_2 = number of items in sample

p = proportion of items in sample possessing characteristic being measured in decimal form or

$$= \frac{\text{number of meters within } \pm 2\% \text{ error}}{n_1}$$

$q = 1 - p$

w = one half of total desired width at a specific confidence interval in decimal form

k = 1.64 for 90% confidence level
1.96 for 95% confidence level
2.58 for 99% confidence level

$\frac{N-n_1}{N-1}, \frac{N-n_2}{N-1}$ = finite correction factor

$\bar{X}_s$ = arithmetic mean of sample

$\hat{\sigma}_u$ = estimate of standard deviation of universe from sample of n_2 items

$$= \sqrt{\frac{\Sigma_z{}^2}{n_2 - 1}}$$

Appendix. Some Statistical Equations Applicable to this Problem, Method of Attributes

The following assumptions will be made:

1. A scientific sample has been picked with no bias caused by method of selection.

2. Universe and sample are Normally distributed.

Other methods utilizing the Binomial distribution yield smaller Attributes samples than this one, which assumes a Normal distribution.

Confidence interval =

$$p \pm k\sqrt{\frac{N-n_1}{N-1} \times \frac{pq}{n_1}} \qquad (1)$$

n_1 = estimate of required sample size =

$$\frac{k^2pq}{w^2\frac{(N-1)}{(N)} + \frac{k^2pq}{N}} \qquad (2)$$

Confidence interval =

$$\bar{X}_s \pm k\sqrt{\frac{N-n_2}{N-1} \times \frac{\hat{\sigma}_\mu}{\sqrt{n_2}}} \qquad (3)$$

n_2 = estimate of required sample size =

$$\frac{k^2\hat{\sigma}_\mu{}^2}{w^2\left(\frac{N-1}{N}\right) + \frac{k^2\hat{\sigma}_\mu{}^2}{N}} \qquad (4)$$

Discussion

F. H. Busch (General Electric Company, Rochester, N. H.): Mr. Dwon and Mr. Morris are to be complimented on a fine paper which will add materially to the rapidly growing body of knowledge covering the application of statistical techniques to the measurement of whr meter performance. These techniques have been developed and researched in great detail by theoretical mathematicians and statisticians. Quality control engineers are working diligently and successfully to reduce this technical knowledge to methods and plans that can be applied to everyday industrial problems. As the methods are applied to a new field, a considerable number of people must learn enough of the fundamentals and principles used in order that proper applications can be made. This paper serves this purpose by illustrating and discussing the use of statistical methods for the problem of measuring the performance of whr meters. Operating meter superintendents will find this paper useful and helpful to the consideration of their own situations.

It is to be expected that various individuals will propose and defend a variety of other procedures for selecting the sample, determining the number of meters in the sample, and classifying or grouping the meters for evaluation. The point to remember is that the number of possible specific sampling plans or procedures is infinitely large though all are based upon a few fundamental mathematical concepts. The requirements and objectives of the particular application will determine the particular details of the best plan for that situation.

The authors have used the concepts of confidence level and confidence interval as a measure of the reliability and precision of the sampling plan to be used. These are entirely valid means for such evaluation, though I have found it difficult for persons who have not studied probability theory to relate these measurements to the needs of a practical application. An alternative approach that I have found useful makes use of probability statements such as the following:

"The quality of meter performance is adequate when the results of the sample-lot evaluation provide assurance such that there is only one chance in ten that the per-cent of accurate meters is less than A%. A may be 98%, 97$^1/_2$%, 97% or any per cent which the operating superintendent considers to be the poorest level of performance that he can accept without taking specific and above normal corrective actions.

This approach results in a larger sample size when the actual level of performance is near A% and a smaller sample size as the actual level is increasingly better than A%.

Since actual results of previous tests provide an evaluation of the probable true per cent of meters in error, it is possible to determine the sample size required for the ensuing year with consideration of the particular situation then existing. This approach does require that the operating superintendent determine the level of metering performance which is adequate and acceptable in his situation. It also assumes that separate, specific, and effective corrective actions will be taken as the actual level of quality is found to be approaching the minimum acceptable.

Many factors must be evaluated in arriving at this minimum acceptable quality level, including technical feasibility, costs of attaining improvement, revenue losses, customer complaints and relations problems, and evaluation of regulatory requirements. However, these are evaluations which operating meter superintendents have been making as a routine part of their jobs for many years. The only new factor is the need to reduce those evaluations to the simple probability statement with a specific minimum percentage of accurate meters being defined and established. Once this is accomplished the particular sampling plan and a program of administra-

Vol
Pt.
195

tion can be worked out with the use of the concepts presented in the paper or with the aid of a competent statistician or quality control engineer.

As a final comment on this paper, I am pleased that the authors recognized that statistical approaches to the selection of domestic meters for test do not result in cost savings until the number of meters in error is insignificant or, stated differently, the accuracy performance is better than minimum acceptable level.

My own experience with the application and use of these quality control techniques in the manufacture and factory calibration of whr meters has been that both better quality and lower cost are realized when they are used as compared to when they are not. It is because of this experience and the conviction that similar benefits, better accuracy in service with lower testing costs, can be achieved by the meter departments of electrical utilities that I commend Mr. Dwon and Mr. Morris for providing this paper for the consideration of their fellow meter engineers.

J. G. C. Templeton (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): The authors are to be commended for their initiative in proposing stratified random sampling as a method of selecting domestic meters for test, and for working out in some detail alternative sampling plans for their company's population of meters. The proposal to group the many types of meters in the population into five classes for sampling purposes is particularly useful. A number of statements in the paper are open to criticism from the point of view of theoretical statistics. Since the paper is not written for or by professional statisticians, however, it would be inappropriate to pounce critically on mathematical infelicities, except where these seem to lead to undesirable practical advice.

1. The authors' sampling plan, and other proposed plans for sampling inspection of meters, seek to give the operating company the information it needs about the condition of its meter population, and to do so with less inspection effort than the traditional system of 100% inspection after a fixed term of years. A properly designed sampling plan can estimate the mean error of a population of meters, and how closely individual meters are clustered about the population mean. Sampling inspection can do these things more efficiently and at lower cost than the traditional method. It can be objected that sampling inspection does not meet another purpose of regular inspection, that of protecting the individual consumer against the risk of many years of overcharges, based on a fast meter not discovered by regular inspection. This point could be discussed at great length, and no doubt it will be before sampling inspection of meters is adopted generally. It should be noted that, as shown by Fig. 3 of the present paper, older types of meters are rapidly going out of service. Once the class I and class II meters are gone, the case for 100% inspection will be greatly weakened.

2. The authors are certainly correct in saying that, when the distribution of meter errors in the population is known, the Variables method permits smaller sample sizes than the Attributes method for equal accuracy of estimation. The advantage of the Variables method is not, however, quite so great as Table II suggests. The ratio n_2/n_1 compares two sample sizes, a sample of size n_1 for estimating percentage defective and a sample of size n_2 for estimating mean error. The fact that n_2 is much smaller than n_1 is partly due to the fact that mean error is much easier than percentage defective to estimate from a sample. It follows that the values of n_2 given in Table V are not adequate for estimating percentage defective with the required precision. Values of n_2 needed for estimating percentage defective in a normal population can be found in reference 1.

3. A further weakness of sampling inspection by variables, not much discussed in text books, is the lack of robustness of the tests and confidence intervals for small proportions defective. Statisticians speak of a statistical procedure as being "robust" when its validity is only slightly affected by moderate departures of of the population from its assumed form. In the present case the critical assumption for the Variables method is the normal distribution of meter errors. If the proportion defective is small, moderate departures from a normal distribution may lead to serious errors in estimating the percentage of defective meters. Calculations carried out by Ontario Hydro for a population of Canadian meters show that, for this population at least, estimating proportion defective by the Variables method gives poor results.

4. In Table III of the paper, three different stratified sampling schemes are given for selecting a sample from each class of meters. A fourth scheme which has some advantages over those given in Table III would be an "optimum allocation" stratified sample, as developed by Neyman and described in reference 2. This method would give larger proportionate representation in the sample to the less accurate meters. The method can be generalized to allow for possible higher unit inspection costs of rural meters, and will show how to get specified accuracy at minimum cost.

A. J. Polaneczky (The Franklin Institute, Philadelphia, Pa.): The subject matter in the paper is of nationwide importance and undoubtedly will receive widespread attention. Unfortunately, we disagree with much of the philosophical presentation; we feel that the misapplication of statistics to the problem at hand invalidates a good deal of the paper. A discussion of the major points of disagreement follows:

1. The paper claims that sampling procedures sacrifice accuracy for economy. This is not necessarily so. There are instances when sampling gives more reliable results than 100% inspection. See page 9 of reference 7 of the paper.

2. The paper claims that the use of sampling presupposes a knowledge of the distribution of items in a universe. This knowledge would be helpful, but is not necessary.[1] The Binomial theory, as used in the paper, is nonrestrictive on knowledge of the universe distribution.

3. There are "Variables" methods, other than the one used in the paper, which do not demand that the universe be normally distributed. For a simple illustration see pages 55 and 56 of reference 7 of the paper, for a discussion of the Tchebycheff and Camp-Meidell inequalities.

4. The definition of a "Scientific Sample" is too restricted. There are occasions when a "biased" sample can give more reliable information than a random sample of the universe. See reference 2, with particular attention to Stratified and Cluster Sampling.

5. The equation developed for the relative size samples required by the Variables and Attributes plan is meaningless. The relative sample size is based on a comparison of confidence limits for the fraction defective calculated using the attributes method, with the confidence limits for the average registration (universe mean) based on the variables method. The relative sample size should be based on a comparison of the confidence limits for the fraction defective calculated using the attributes method with the confidence limits for the fraction defective based on the variables method. For the mechanics of calculating the fraction defective using variables data, see reference 3.

Unfortunately, the incorrect comparison, noted above, invalidates much of the latter sections of the paper.

6. It is not possible that the distribution of items in a universe, or sample thereof, be normalized by taking a sufficiently large sample. It is only the distribution of sample averages which is normalized.

7. The calculation of the confidence range, based on engineering experience, as illustrated by the authors (±2,890 meters out of 440,000) is unkind to the meterman. The number of defective meters was 5,780. With any kind of past history, the estimated confidence limits should be pretty good. The actual confidence limits, though, cannot be definitely tied down, unless more of the past history data is made available.

8. Again, in the Appendix of the paper, the universe and sample need not be normally distributed to make use of an attributes plan.

9. Equation 3 is incorrect. Sigma should be squared and the radical removed from n_2. The equations presented are concerned with confidence limits of the mean. As such, if the sample size is sufficiently large (>30), the restrictions on normality can be dropped.

C. L. Lucal (Ohio Power Company, Canton, Ohio): The authors are to be commended for presenting this approach to an evaluation of the accuracy of whr meters in service. As a result of the method, data obtained from tests on a small number of meters, properly selected, are the barometer for the performance of all meters of the same type in service.

Investigation of the accuracy of whr meters by classes was started before statistical sampling was presented to meter engineers. The data obtained were based on 100% samples of geographical areas. The number in the samples amounted to 2% of the meters in service.

In the work that has been done, all data were based on full load results. Tentatively, the limit of acceptability is that less than 2% of the sample may be outside the limits of 98% and 102% accuracy.

No attempt had been made to segregate urban and rural data, but it was evident that meters in areas of large rural content showed poorer performance than those in strictly urban areas. This was emphasized by the fact that the meters in classes IV and V were excellent when compared to those in classes I, II, and III. Rural and urban data were segregated in subsequent 100% samples of geographical areas. These data confirmed former evidence that meters in classes I, II, and III were affected to a much greater degree in rural areas than the same class of meters in urban areas, and is attributable to lightning exposure.

The performance of classes IV and V was not significantly different for the rural and urban areas. This is an indication that the surge-resistant magnets were not affected by lightning exposure in the rural areas.*

It should be pointed out here that all data in the foregoing discussion were obtained from meters that had been in service for 8 years. From these data it was concluded that:

1. Only meters having surge-resistant magnets should be installed in rural areas.

2. The test schedule for meters in classes I, II, and III could not be extended beyond the present 8-year schedule.

3. The performance of classes IV and V indicated that the test schedule could be extended.

4. The conclusions of items 2 and 3 were not compatible with area testing by the mobile laboratory method and would compel adoption of a due-date method, the cost of which might offset savings derived from a lengthened schedule for classes IV and V.

5. Economies in periodic schedules could be made by extending the schedules, but the most benefit could be attained when classes I, II, and III had been eliminated.

6. Periodic testing did not eliminate the cost of testing 96 out of 100 meters to find the 4 that needed attention.

Although the 100% sampling method afforded valuable data, it lacks the credence of the statistical sampling method which can be proved mathematically. This is important, for the statistical method has been found acceptable in many regions, whereas the data obtained through the 100% sampling method lacked the stature for acceptability. The statistical method also affords the probability that, in the long run, greater economies can be effected than by extension of periodic schedules.

When statistical methods are used for quality control of manufactured products it is assumed that the universe is homogeneous, i.e., that all the tin cans coming from one machine in a day's run are the same size, shape, color, and the last one made that day can be no older than the first by more than 24 hours, so time is not a factor. However, time is perhaps the most important factor when statistical sampling is used to draw inferences about the sustained accuracy of meters in service. This observation resulted from statistical sampling tests that were made.

It must be recognized that the average length of time in service since last date of test for meters in a statistical sample taken from a universe that has been on an 8-year schedule will be 4 years. It is for this reason that the performance data obtained by the statistical sampling method appears, on a percentage basis, to be better than that obtained by the 100% sample in a geographical area, the word "better" meaning that a smaller percentage were outside the 2% acceptability limit.

It seems necessary, therefore, to make an analysis by class of the meters that were outside the acceptability limit versus the length of time since last test. For classes I, II, and III about 1% were outside the limit at the end of 1 year, about 4% were outside the limit at the end of 8 years, and about 7% at the end of 11 years. This is evidence that there is a relation between accuracy and the years since last test.

A similar analysis for class IV shows that about 3% were outside the limit at the end of 8 years, a matter that should cause concern and indicates that, in the future, this analysis should be carried still further in that the data for each manufacturer's meters in the class should be analyzed.

The data for class V show excellent performance for an 8-year period. Here, again, the same precaution of detailed analysis is recommended in the future for this class.

Statistical sampling is a policing action regarding sustained accuracy over protracted lengths of service, and only by detailed analysis can the effects of time on a particular type and make be evaluated.

Once it has been established that a certain class of meter will not retain its accuracy for more than an 8-year period, it should not be necessary to include such meters in a statistical sample, thus saving the cost of testing such meters. It is presumed that these meters are placed on a regular schedule or are replaced by modern meters.

A saving can be effected by the statistical sample method through reduction of personnel and equipment, but the greatest benefits can accrue only when all the older classes of meters have been replaced with those which have inherent stability over a period of 30 to 40 years.

Referring to item 4 of the first heading under "Conclusions" in the paper, the statement should be qualified in that rural meters in classes I, II, and III show evidence of higher frequency of error than classes IV and V when compared to urban meters. Under item 5 of the same heading, the last clause of the last sentence would be more realistic if written, "1/7 of which will be tested in each of the next 7 years." Under this same item, it is difficult to agree that the 100% sample in a geographical area tells us nothing about the other 87½% of meters on the system. It is true that the 100% sample tells us the condition of the meters that have been in service for 8 years; we know, too, that the meters were within the accuracy limits when they were first installed. Consequently, it is a logical conclusion to feel that meters less than 8 years in service will have accuracies poorer than when they were originally installed, but in no instances poorer than at the end of 8 years. In other words, the deviation from original accuracy limits is a progressive situation. The only exception to this conclusion might be for a modern meter which it is believed will have a sustained accuracy for a period of 30 or 40 years.

W. C. Harrison (Virginia Electric and Power Company, Richmond, Va.): The authors have presented an excellent treatise on the use of statistical mathematics in the selection of whr meters for test.

For many years, the art of metering has been a highly specialized one, and many metermen have not had the opportunity of becoming acquainted with the statistical methods that have been employed in many other fields to solve test problems. To the meterman, upon first glance, the applications as stated in the report would indeed seem to be complex, and the initial reaction may be one of discouragement with the resulting failure to pursue the subject further. It is to be pointed out that even a brief insight into the use of statistical mathematics will prove a revelation for it will be found that all of the equations and calculations that might be employed will tend to prove that the judgments based on long years of experience with meters will be correct.

The use of such a plan as outlined for the selection of meters for test may not prove applicable where there are only a few meters to be considered, for the greatest benefit will be derived by those who are confronted with the enormous problem of caring for many thousands of meters. However, those with only a few meters could profit by a working knowledge of the sampling procedure for it will prove useful in many ways.

The domestic whr meter lends itself admirably to the sampling techniques. They are found in great numbers, their types are few, and their applications are similar to such an extent that the results obtained within one area of the country would even be useful for study purposes in other sections of the country. In fact, were this plan generally adopted, the interchange of information between groups would prove most valuable.

It is suggested that the meterman himself does not necessarily have to be an advanced mathematician, for one can usually find among his fellow engineers a mathematician who could quickly set forth the problems and the equations that may be required in the specific case. Indeed it is best that one, not too familiar with meters, be permitted to set up the basic formula for he would not be biased by knowledge accumulated from years of experience with meters. On the other hand, the meterman, knowing the characteristics of the various types of meters, would derive real pleasure in analyzing the mathematical proofs that his decisions through the years have been reasonably accurate.

G. A. Palmer (New England Power Service Company, Boston, Mass.): The authors have presented a very useful paper on the control of meter accuracies by statistical analyses of sample tests. The subject is a very live one in many electrical utility companies since the method holds great promise both for economy and for a gradual but significant improvement in meter performance. In the New England Electric System we have studied the sample test procedure for some time, with trial runs in two operating divisions. Generally our approach and our conclusions agree with those of the authors. Naturally there are differences, but no major ones, in details of procedure and in approach to the justification for this test method.

A difference in emphasis lies in our belief that sample testing can be justified by the fact that if proper action is taken on the results of the sample tests, meter accuracies can be improved over those achieved by periodic testing, regardless of how heavy the periodic test schedule may be. Of course the expected economies are welcome, but they are not the chief sanction for this procedure.

To comment on this paper is to comment on the subject of sample testing itself, as applied to whr meters. Accepting the procedure in its broad outlines, and accepting the mathematics which confirm the procedure, there remain some fundamental questions which should be raised. The answers to these questions should support the validity of the program rather than undermine it.

The aims of a modern test program must be that

1. Good meters are accepted with a minimum of effort.
2. Poor meters are corrected or replaced.

The question is: How do we find the poor meters? Let us not raise the question here as to the exact tenth of a per-cent error that is the dividing line between good and poor meters.

The authors answer, by a statistical approach. A sample test of the whole universe of meters analyzed by age, location, or, if necessary, by additional factors, will tell us which meters contributed more than their share of the total error.

There is no question but that a sample test can be used for quality control of any homogeneous group such as can be found on the production line of a factory, whether the product be meters or billiard balls. However, it does seem to me that certain modifications in thinking about sample testing must be made when the population is that of meters in service.

A company maintaining domestic whr meters on an 8-year schedule has performance data for 25% of these meters, collected in any 2-year period. Although in a number of places the authors admit that these performance data have given them information, they tend to disregard this information because the meters have not been selected according to the laws of random sampling. I do not believe that we are justified in throwing away the data we have so conscientiously collected over these many years. Mathematically it may be true that a 100% sample from one eighth of the total meter population does not justify any statistical inference about the remaining seven eighths. This implies that we are studying unknown devices under unknown conditions. Let us not adopt in our philosophy hypotheses that we do not believe in our everyday working life.

Every meterman knows that there have been improvements in meter design, and that the 1920 meter is not as good as the 1950 meter. Additional statistics are not required to establish this. We have 25 years of such statistics. In many types of meters we have already taken 100% sample. What more can we ask?

There is another aspect of the procedure of sample testing of whr meters which seems to me fundamental and which does not appear covered in this paper.

Professor Wilks[1] points out that in any sampling procedure correct conclusions depend not only on the method by which the sample is selected but on the process by which information is obtained on the sample once it is selected. Most of the emphasis so far has been placed on Stage I, the method of selection. But to quote Professor Wilks:

> "Stage II is the more basic of the two stages in the sense that it is at that stage when the degree of accuracy and precision (sometimes called validity and reproducibility) of the actual measurements themselves must be established. These cannot be established by merely assuming that the measurement obtained in a single test represents what we are usually tempted to think it represents. If measurements are repeated, variability is found and usually some of this variability is attributable to assignable causes (that is, causes which can be located) which may not have been suspected initially. Stage I sampling laws depend on making use of measurements whose accuracy and precision has been established at the stage II level."

This leads us to ask: When testing is done under differing conditions, as in a large company, with several test locations, how can it be determined how much variability in results is due to variability of meters, and how much due to variables in test equipment, technique, or personnel? A severe control of all factors is necessary, but it may be found that such control is difficult to maintain. Even with this control it must be admitted that variations in meters and test equipment make exact reproducibility of test results practically impossible. This seems to me particularly important when using the method of Variables.

In any statistical analysis the first step describes the universe and the second step proposes action. Using the method of Attributes, with a comparatively large sample, bases for corrective action, for acceptance or rejection, do not appear to me to be too difficult to establish. If our limits are ±2% the simple fact that a meter is or is not within these limits is sufficient.

With the method of Variables, however, the small sample calls for close analysis. I question whether the indicated degree of error is sufficient. I believe it is necessary to know the departure from previous calibration, that is, how much has each meter changed. Perhaps how much change per year.

It is impractical to adjust all meters to perfection, but with a sample as small as that stated to be sufficient for the method of Variables certainly the possibility that some meters were installed 1/2% slow and others 1/2% fast cannot be disregarded. Whether the meter $1^1/_2$% slow has changed 1% or 2% since last calibration should be of interest to the analyst. This requires reference to past history.

Referring again to Prof. Wilks, if some part of meter variability is attributable to assignable causes, should not this fact be considered in any analysis of the sample test results? If so, it is necessary to know in detail the history of the meter in service.

The question is, are we justified in using the method of Variables for determining performance of whr meters in service?

I should like to repeat that on the general program and on the conclusions reached we are in wholehearted agreement. I should like to thank Mr. Dwon and Mr. Morris for establishing the adequacy of a sample meter test program as a substitute for the inefficient and cumbrous periodic meter test schedule.

1. **Wilks.** *Proceedings*, American Society of Testing Materials, Philadelphia, Pa., 1948.

L. M. Keever (North Carolina Utilities Commission, Raleigh, N. C.): In this paper the authors have dealt, in a very forthright manner, with a subject which should be of great interest to all those who have to do with single-phase whr meters. They are to be congratulated for making such a fine contribution and bringing this information in a very concise manner to many who can use it to good advantage.

Most of us have been aware for a number of years that a lot of time and energy is being wasted on testing, on a periodic basis of 5 or 8 years, these modern whr meters which are now being produced. One solution to this problem is a longer period between tests, but the question immediately arises as to what to do about the older types of meters which ostensibly do not have the qualities of sustained accuracy over long periods and with large overloads. Longer periods between tests obviously is not the logical answer.

We believe that sampling based on sound statistical principles and properly administered will give the utility and the regulatory body concerned a more intelligent evaluation of the condition of the utility's meters than can be gained by the present method of periodic testing. Analysis of the data from sampling tests will focus attention on the types of meters which have poorer performance characteristics and will help the meter department to convince management of the necessity of early retirement of these meters.

The authors have taken the position, and justifiably we think, of emphasizing the saving in meter test expense on the part of the utility which will ultimately be effected by the use of sampling in lieu of periodic testing. This is unquestionably an important feature of this system. We cannot overlook, however, the advantage of having rather accurate knowledge of the performance characteristics of all the various meter types which we have in service in a utility system. In what other way could we so accurately determine the susceptibility of the age group I, II, and III meters to the effects of exposure to lightning surges as is demonstrated in the authors' Table I. The much greater percentage of these age groups which are more than 2% fast in rural areas as contrasted to urban areas is emphatic when the small difference in these percentages is noted for age groups IV and V. It has been well known to all of us that the newer types of meters have characteristics of design which make them less susceptible to the effects of lightning surges, but it is only when we review the data on sampling tests that we have this fact brought so forcibly to our attention.

It has been assumed in general, as well as by the authors in this paper, that in the various age groups of meters which they have used for classification all manufacturers' types in each age group perform equally well. While this assumption is true in a general way, it has been found by analysis of sampling test data by meter types that specifically this assumption is subject to error for age groups I, II, and III. For example, if the average performance of a given age group indicates that 10% of this age group are more than 2% fast it is possible that this percentage is affected heavily by the poor performance of one type of meter in the group. On the other hand if another age group shows a large percentage of slow meters, this poor showing could be influenced strongly by a single type in this age group. Such discrepancies are not apparent to any appreciable degree in the test data of age groups IV and V.

We feel, therefore, that if a realistic approach is made in the analysis of these test data such analyses should be made by meter types rather than by age groups.

We further feel that a more accurate determination of the condition of all the meters in a utility system can be made if the sampling can be done on the basis of meter types rather than by age groups.

There is one point in connection with the substitution of scientific sampling of meters for test instead of the periodic system of testing on which the authors have not touched. This is the manner in which the system will be administered. Some standard of performance must be adopted whereby all meter types or age groups whose accuracy is shown by the sampling test data to be equal to or better than the standard will continue on sampling. Other types or age groups whose accuracies do not meet the standard will be tested on an accelerated periodic basis. In this group will be some types whose performance is sufficiently poor that they should be retired and replaced by modern types of meters. By this method if any group of meters after recalibration and modernization shows an improvement in operating accuracy to a point where it meets the standard established, then this group is placed on sampling rather than periodic testing. Similarly if any group in successive sampling tests falls below the standard such group would be placed on the accelerated basis of periodic testing.

It should be emphasized that the savings in meter testing costs envisioned by the authors will not be realized immediately upon the institution of this sampling procedure. During the first years of such procedure the accelerated periodic testing may require the testing of as many meters as are now being tested under normal procedure. Only after all the inherently inaccurate meters in the system have been eliminated will the full benefits of the sampling method be realized.

Larry Dwon and J. A. Morris: The value of a technical paper is appreciably enhanced by such honest and open discussions as have been advanced by F. H. Busch, W. C. Harrison, L. M. Keever, C. L. Lucal, G. A. Palmer, A. J. Polaneczky, and J. G. C. Templeton. Each of these gentlemen is recognized for his experience and knowledge of domestic meters and/or statistical sampling procedures.

The authors' presentation was prompted principally by the thought that perhaps there are some expert meter men who might not be adequately familiar with statistical methods and would, therefore, tend to shy away from investigating them. Thus, an example of how this powerful tool could be used seemed appropriate. This paper is a condensation of an internal report, which had for its basis these very concepts with relation to meter personnel in the AEP system. Experience with the report seemed to indicate that similar personnel in other areas of the country would welcome such a treatise. Therefore, it should be realized that this paper did not intend to cover all aspects of theoretical statistical sampling procedures, and it is for this reason that several references to standard texts have been included. As a consequence, it was anticipated that the more important omissions would be brought out by the discussers, and for this we thank each of them for having done so.

Particular attention is directed to Mr. Busch's remarks, which seem to cover most of the topics discussed, and in effect would constitute an ideal closure. It is well that Mr. Busch emphasized the advisability of learning fundamentals and principles of statistical sampling because they are rapidly becoming important tools in engineering. Mr. Busch's reference to the alternate approach of using probability statements instead of confidence levels and intervals is well taken, and certainly such approaches should be used by those who believe that they are more easily understood. Mr. Busch also makes very good reference to the many factors that must be evaluated in arriving at minimum accepted quality levels. Here is where statistical sampling may prove to be a valuable tool to help learn more about factors affecting meters in service, rather than simply to accumulate a mass of data. Statistical sampling methods may be used not only to determine meters for test, but also to excerpt from mass data information which may be considered too troublesome to obtain when faced with the review of all of it.

Mr. Templeton cautions us that the sampling inspection does not "protect the individual consumer against the risk of many years of overcharges based on a fast meter, which may not have been discovered by regular inspection." This is an obvious difficulty. The full value of statistical sampling procedures will not be derived until a population of meters is in existence which is mostly free of inaccurate meters. Mr. Templeton very accurately points out that the Variables method will not result in as small a relative sample as the n_2/n_1 ratio suggests in Table II. This point was discussed briefly in the paper and covered by the statement, "It should be noted, however, that the above formula exaggerates the n_2/n_1 ratio because the best attributes sample is not utilized as explained previously." Mr. Templeton points up a weakness of sampling inspection by variables, which should be taken into account. However, it would still appear that other advantages of the method outweigh the disadvantages. Mr. Templeton's reference to an "optimum allocation" stratified sample is a good one. As Mr. Busch pointed out in his discussion, there are many sampling plans that can be made, each having some particular advantage and disadvantage. It is up to the meter engineer and the statistician to determine what is best for the particular situation.

Mr. Polaneczky favored us with a discussion which we are happy to include because it points out quite positively that there is more to statistical analysis than what this paper had as an objective to show. The authors believe that Mr. Polaneczky did not appreciate that our paper did not intend to delve into the elegant phases of statistical philosophy. Our attempt was to acquaint an audience of meter men, who probably know little about elementary statistics, with this valuable and powerful tool in a specific field of application. In our attempt to meet the needs of this audience as simply as space limitations permitted, we may not have stated precisely some of the more philosophical facts about the subject. If we did not do an adequate job, the error certainly should be called to the reader's attention. However, we cannot agree that the points raised by Mr. Polaneczky are so badly distorted and misapplied, as he states. The authors wish to call the reader's attention to Mr. Polaneczky's text references, which deal with the deeper concepts that will certainly have to be taken into account as statistical procedures are applied to the meter testing problem.

Mr. Lucal, to whom the writers are indebted for much of the actual data used in the paper, points out that investigation of the accuracy of whr meters by classes was started before statistical sampling was presented to meter engineers. This was done on the basis of 100% samples in small geographical areas. This is acknowledged and merely confirms the value of sampling procedures. Whereas Mr. Lucal was able by such methods to obtain data about meters in a specific location, the same kind of information could have been obtained by statistical methods; but whereas in his situation he could conclude really only that the findings pertained to that geographical area, the statistical method would have allowed conclusions that pertained to the entire universe of meters in the company. Particular attention is directed to Mr. Lucal's very illuminating conclusions regarding meters. Mr. Lucal also makes mention of the homogeneity of the universe as used in quality control of manufactured products. Statistical methods can be used with nonhomogeneous universes, as have been pointed out by Mr. Templeton in his reference to statistical sampling.

Mr. Harrison cautions that the statistical sampling procedure may not prove applicable where there are only a few meters to be considered. This certainly is a worthy observation because statistical methods give the most help when they are applied to a mass of data from which information is desired at less expense, but at the risk of some error. Mr. Harrison brings out a very good point regarding the establishment of methods of interchanging information among groups throughout the country if standardized sampling techniques could be properly agreed upon. Mr. Harrison also makes a very good point when he suggests that the sampling plan might be worked out better by someone who is not familiar with meters in order to assure objectivity and an unbiased probe for correct information. However, the statistician would have to be guided by the meter expert in order to learn enough about the problem to properly establish the required sampling plan. This is essentially what the team of Morris and Dwon consisted of, the former a meter expert, the latter having some knowledge of statistical sampling procedures.

Mr. Palmer asked a very pertinent question, "How do we find the poor meters?" This, of course, can be achieved in many ways, but certainly cannot be done by the statistical sampling procedure. The latter will only determine the groups of meters predominantly in error and factors which may be instrumental in causing these errors. Once this is established, then the only way to determine all of the poor meters is to test all of them in that area or that group. As has been pointed out by other discussors and in the paper, the sampling procedure will be most effective when the universe contains meters of insignificant inaccuracy. Mr. Palmer's reference to the authors' disregard of information obtained from performance data requires a comment. In the paper, we intended to stress that if information is obtained about meters located in a concentrated area, any inferences that are made from such observation, theoretically or practically, cannot be carried over to meters in another location of the company. It isn't that the authors would disregard performance data, but it isn't possible to draw a conclusion from a test at location *A* of a miscellaneous group of meters which would be valid for another miscellaneous group of meters at location *B*. By no stretch of the imagination can one make such an inference. However, with an equivalent number of tests on meters picked at random from the entire universe, then similar information would be obtained, which then would be applicable to all of the meters on the system with certain error limits.

This is the main point that the authors were endeavoring to emphasize. Mr. Palmer brings out a very good point, however, regarding procedures of testing under different conditions in a large company. Certainly the Variables method depends on reproducibility of valid tests in all locations. Another good point that Mr. Palmer brings out is the impracticability to adjust all meters to perfection. The writers acknowledge that the subject of whether Variables or Attributes methods should be used is not a closed subject and, therefore, the question, "Are we justified in using the method of Variables for determining whr meters in service?" is not unreasonable. It will have to be determined by the needs through adequate discussions among the industries. We believe, however, that the Variables method, mainly because of its reduced sampling needs, should be the proper approach for our purpose.

Mr. Keever notes that is a realistic approach is made in the analysis of test data, it should be made by meter type rather than by age groups. The writers have no preconceived notions precluding other groups into which sampling information should be placed, and certainly meter type is one. The wide scope that is made available for analyzing the many factors affecting meters in service makes the area of meter testing exceptionally intriguing.

The writers are especially fortunate in having such prominent meter engineers and statisticians discuss this paper and feel obliged to thank all of the discussers for their excellent contributions and ideas.

Field-Strength Measurements in Parallel-Plate Precipitators

J. S. LAGARIAS
MEMBER AIEE

COMMERCIAL precipitators are faced with the problem of efficiently collecting dust particles of sizes ranging from hundredths of a micron to several hundred microns in diameter. This span of over ten thousand, in size, imposes a wide range of collecting conditions which make it difficult to accurately predict precipitator performance. The nature and magnitude of the forces acting on particles must be determined if one is to understand and improve precipitator design.

Electrostatic precipitators are generally tubular or of parallel-plate design. In the former, calculations can be made of the forces involved in solids removal. In parallel-plate precipitators, calculations are more difficult because the geometry does not readily lend itself to a solution for conditions wherein the space charge, dust loading, and field strength are variables. Because of the many conflicting factors present in commercial installations, it is necessary to isolate and study the many variables. This report describes studies made with experimental parallel-plate precipitator assemblies to determine the field strength distributions, the effect of dust loading, and to evaluate wire spacing in terms of known parameters.

Field strength was determined by measuring the charge on spherical steel spheres dropped through an electrical field. This technique has been used in several different forms. Pauthenier and Moreau-Hanot made many of the initial investigations of field strength in tubular electrodes.[1] In similar experiments, Penney investigated the effect of abnormal corona discharges on particle charge.[2] Cooperman used small metal spheres as missiles to measure fields and current densities.[3] In this investigation, emphasis was placed on using the dropping sphere technique to obtain field strength patterns in parallel-plate configurations and to determine the effect of dust loading on field strength.

Measurements were made with particles much larger than would usually be found in conventional precipitators but small enough so that their presence would not materially affect the field-strength dis-

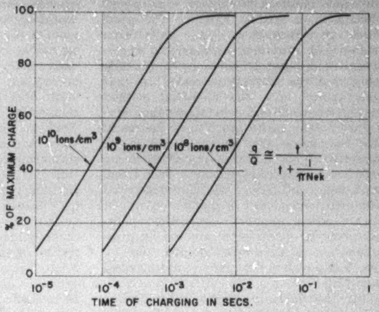

Fig. 2 (right). Ion density versus time on particle charge, field charging only

tribution in an 8-inch plate-to-plate geometry.

Description of Apparatus and Tests

Initial studies to determine charge as a function of field strength and particle size were made with a small precipitator section consisting of a 20-mil-diameter electrode centered in a 4.75-inch-inside-diameter steel tube open at both ends. The apparatus is shown schematically in Fig. 1. Spherical steel balls were dropped through the tubular-type electrostatic precipitator unit parallel to the discharge wires and the grounded cylindrical collecting electrode. Tests were made in still air at ambient temperature and humidity.

The spheres passed through the electric field between wire and collecting electrode and were caught in a Faraday cage. The charge on the ball was transferred to the cage and measured with an electrometer. The balls obtained their equilibrium charge since their fall was long compared to the charging time.

The per cent of saturation charge which a sphere will receive depends on the product of the ion density, N, and the charging time, T. The spheres were in the electric field region for 0.19 second. In the tests investigated, the ion density ranged from 1×10^8 to 1×10^9 ions/cm³ (centimeter) giving an NT factor and exposure time of 1.9×10^7 to 1.9×10^8. Fig. 2 illustrates the effect of ion density on per cent of charge on each sphere. The ion density and exposure time was sufficiently high so that the particles were fully charged for all practical purposes. The magnitude of the charge was a function of the field strength and the particle size.

All tests were made with the discharge electrode at negative polarity. At high field strengths, a noticeable deflection of the spheres occurred and it was necessary to move the cage accordingly. Spheres which were dropped too close to the collecting electrode and struck the walls before passing through the discharge electrode section, immediately gave up their charge and were effectively neutralized. All measurements were made of particles which passed through the precipitator section before striking the grounded electrode. Those particles which did strike the collecting surface were substantially neutralized.

It was assumed that the charge on each sphere represented the point of highest field strength through which the sphere passed. The deflection was always from a region of higher to lower field strength. In all instances, the sphere fell parallel to the discharge electrodes.

For balls greater than one micron, the charge on each sphere is proportional to the dielectric constant, the local field strength and the square of the ball radius.[1] This holds up to the size where the presence of a large charged sphere materially distorts the electric field. Field charging was the mechanism of charging, diffusion charging being negligible under the conditions involved.

Field-Strength Theory and Measurements

Field-strength measurements made in tubular precipitators can be used to check theory since calculations can readily be made. It is more difficult to calculate field strength for parallel-plate precipitators, however. In the present analysis, experiments were made with a tubular precipitator to check the reliability of the experimental technique. The field strength for parallel plate precipitators was then measured.

Equipotential surfaces in parallel-plate arrangements have been made using a probe technique but it is of interest to know the actual field strength since this is the driving force which is precipitating the dust from the gas stream.[4]

Tubular Electrodes

For concentric electrodes, with ionic space charge present, the distribution of the electric field strength, E, may be obtained from Poisson's equation written as

$$\frac{dE}{dr} + \frac{E}{r} - 4\pi\sigma = 0 \tag{1}$$

where σ is the volume space charge. The space charge is generated from corona emanating from the smaller of the two electrodes, and can be written as

$$4\pi\sigma = \frac{2i}{KrE} \tag{2}$$

where i is the current per-unit length of wire at a distance r from the wire since the ion current is

$$i = 2\pi r\sigma \times \text{ion velocity} \tag{3}$$

This solution to this equation as given by Thomsen is[5]

$$E = \sqrt{\frac{2i}{k} + \frac{C^2}{r^2}} \tag{4}$$

In the case where there is no current flow, this reduces to

$$E = \frac{C}{r} \tag{5}$$

which is the solution for the static field strength in concentric electrodes with

$$C = \frac{V}{\ln R_2/R_1} \tag{6}$$

and V being the potential difference be-

tween electrodes. R_2 and R_1 are the outer and inner radii, respectively, of the electrodes.

For large values of r, the first term in equation 4 is large compared to the second and a reduction to the generally used simplified form is possible:

$$E=\sqrt{\frac{2i}{k}} \tag{7}$$

The field strength is essentially independent of the radius throughout most of the outer region of the annular space. In the course of the investigation, it was necessary to calibrate the equipment and Fig. 3 indicates the field strength as determined in this manner and as checked experimentally. Results of this type indicate the validity of measuring field strength by the dropping sphere technique.

Equation 4 is applicable close to the wire but reduces rather rapidly to equation 7 at a short distance from the wire. It is seen that an essentially flat field strength region exists between electrodes. Fig. 4 illustrates the uniformity of the field between electrodes as measured with 1/8-inch- and 3/16-inch-diameter spheres.

Effect of Dust Burden

The presence of dust or solid particles in the gas stream will distort the field-strength distribution still further because of the lower mobility of the dust particles. As developed by Rose and Wood,[6] Poisson's equation is

$$\frac{dE}{dr}+\frac{E}{r}-\frac{2i}{krE}-pES=0 \tag{8}$$

where p is the particle charging factor involving the dielectric constant, D,

$$p=\left[1+2\frac{(D-1)}{(D+2)}\right]$$

and S is the surface area of the dust particles per-unit gas volume.

The solution to this equation is

$$E=\frac{1}{r}\left[\left(\frac{i}{kp^2S^2}+C^2\right)e^{2pSr}-\frac{2i}{pSk}\left(r+\frac{1}{2(pS)^2}\right)\right]^{1/2} \tag{9}$$

Expanding and assuming that pS is small:

$$E=\left[\frac{2i}{k}\left(1+\frac{2pSr}{3}\right)+\frac{C^2}{r^2}\right]^{1/2} \tag{10}$$

which reduces to equation 3 when there is no dust present. For the case where there is dust present in a tubular electrode, the following equation may be used in the region near the plate:

$$E=\sqrt{\frac{2i}{k}\left(1+\frac{2pSr}{3}\right)} \tag{11}$$

It is seen that the presence of dust will increase the field strength assuming the discharge current is constant. The current, however, is not independent of the dust loading.

If spherical particles of mean radius, r_0, are assumed, then equation 11 for tubular electrodes can be written

$$E=\sqrt{\frac{2i}{k}\left(1+\frac{pLr}{\rho r_0}\right)} \tag{12}$$

where

L = dust loading per-unit volume of gas
ρ = density of the dust

The effect of loading on precipitator performance can be estimated in this manner.

PLATE-TYPE ELECTRODES

An examination of the field-strength distribution in parallel-plate electrode arrangements is of special interest since most commercial heavy dust precipitators are more difficult to calculate because of the complications of geometry.

Troost has shown[7] that if equation 7 holds, then the field strength may be given as

$$E=\sqrt{\frac{8iD}{kB}} \tag{13}$$

where

D = distance between wire and plate
B = distance between adjacent corona wires
i = current per-unit length of wire

for a parallel-plate arrangement. This assumption is based on a triangular field distribution and assumes no field exists outside of this region which is, of course, not the case. It is seen that for the condition where the distance between wires is four times the distance between wire and plate the field strength will be essentially the same as that for concentric electrodes.

The field strength of a plate-type arrangement was measured experimentally using the measurement of charge technique as shown schematically in Fig. 5. Steel spheres were dropped parallel to the discharge electrodes at various distances from the plates and discharge electrodes and the field strength determined by the magnitude of the charge on each sphere. Each measurement was the average of ten or more measurements giving good reproducibility. Variation in charge between individual measurements was approxi-

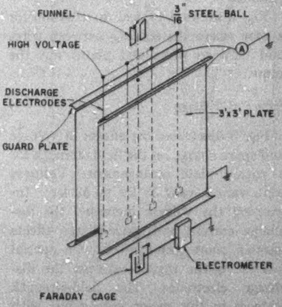

Fig. 5. Parallel-plate precipitator

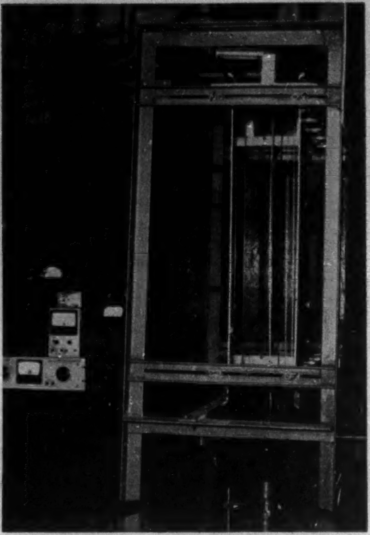

Fig. 6 (left). Parallel-plate field measuring equipment

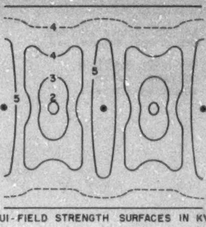

Fig. 7 (right). Field-strength distribution in air. Wire-to-wire spacing, 4 inches; plate-to-plate spacing, 8 inches; voltage, 53 kv, negative

mately ten % but the average values were reproducible within 5%. Day by day reproducibility was consistently good after edge effects were minimized. The equifield strength surfaces were obtained by connecting points of equal field strength. The test apparatus used is seen in Fig. 6.

The charge on the spheres was taken to represent the maximum field strength encountered which would be at the point where the sphere entered the influence of the electric field. That this is representative of the field is shown by the excellent agreement in the tubular precipitator arrangement between the field calculated using equation 4 and the experimental results.

Fig. 7 shows a typical distribution for a case where the spacing between wires and between wires and plates was the same.

Effect of Voltage

Fig. 8 illustrates the effects of voltage and space charge on the field strength for a parallel-plate arrangement. Voltages were varied from 33 kv to 53 kv. Increasing the voltage increased the discharge current and space-charge effects became more pronounced. Of special interest is the region between the discharge electrodes. The field-strength surfaces in this region spread out with higher current densities while the field region between wire and plate remains narrow. Field-strength lines were determined by connecting points of equal field strength. The dashed line srepresent field-strength lines near the plate. Data in this region were difficult to obtain because a slight deflection of the spheres caused them to strike the plate and give up their charge. The field strength tended to even out near the plate. The field strength near the plate was lower at points midway from the wires than directly opposite the wires.

Effect of Spacing

The effect of wire-to-wire spacing on the field strength is illustrated on Fig. 9. As the spacing between wires increases, there is a general spreading of the field from the mid-point between wires rather than from the wires themselves. A doughnut effect beings to show up as the spacing is increased.

Field Strength in the Direction of Gas Flow

To an entering dust particle traveling along a path parallel to the plates, the field strength will be a function of position varying with time and with distance

from electrodes. It is evident from Fig. 9 that the field strength directly between wire and plate does not change for the wire-to-wire spacings investigated. The field between wire, however, is highly sensitive to the spacing. Fig. 10 compares the field strength between wires at a distance of 1 inch from the wires. The peak field strength directly opposite the wires is essentially the same for all wire-to-wire spacings. The dips in field strength between wires, however, are much greater for the larger wire-to-wire spacings. The average field strength close to the wires is higher for the small wire-to-wire spacings. For high field-strength applications then, it is desirable to have the wires close together. This would reduce the reductions in field strength between electrodes.

Fig. 11 shows the field-strength variation with distance parallel to the plates at a distance of 2 inches from the discharge electrode. The dips between electrodes are not as pronounced as the collecting electrode is approached. This smoothing of the field still shows an increased average field strength for the wires which are closely spaced.

Wire Spacing on Current-Voltage Characteristics

As the spacing between wires is decreased, however, there is an interaction between electrodes in which the field emanating from a wire tends to suppress the current from adjacent electrodes. Fig. 12 shows the current-voltage characteristics of a flat-plate precipitator section as a function of wire-to-wire spacing. This would result in a decreased operating range in commercial precipitators and will make control of a precipitator with closely spaced discharge electrodes a little more difficult than with more widely spaced wires.

Fig. 13 illustrates the manner in which the total current/sq ft (per square foot) of plate surface area is affected. In spite of the wide range of wire-to-wire spacings tested, the current/ft of surface area is essentially independent of the wire spacing.

At still lower spacing, however, on a given precipitator length, the interaction between wires will reduce the current at a greater rate than the increase resulting from using more wires. The total current per-unit plate area will thus be reduced.

As the spacing is increased above 8 inches, very little additional benefit is achieved. The increase in current per wire will be slight compared to the increased area which each wire must service again reducing the current per-unit plate area.

In practice, the minimum spacing to be used is dictated by a number of factors: the cost of installing and maintaining additional electrodes, the increased steepness of the discharge characteristics leading to a smaller operating range, and the advantages to be gained therein. In general, however, increased field strength may be obtained by reducing the spacing between electrodes as indicated by Fig. 10 and 11. Since this is the driving force tending to remove particles from the gas, a high electric field is usually desirable. Each precipitator installation has its own unique problems, however, which means other factors such as type of dust, loading, resistivity, etc., must also be considered.

Effect of Dust Burden

The field-strength surfaces shown in Figs. 7–9 were taken in a dust-free atsphere. The question arises as to the

effect the presence of dust will have on the field-strength pattern. The mobility of charged dust particles will be many times lower than that of gaseous ions because of their greater mass and increased resistance to flow through the gas. The presence of the dust will produce a field due to the slower moving space charge.

A small parallel-plate precipitator was constructed in which controlled dust loadings could be obtained. The field strength at several points was determined using the dropping sphere technique. Five widely different materials were used as the dust burden. The results are tabulated in Table I. The most significant effect of dust loading is the manner in which the current is changed.

The primary effect of dust loadings was to increase the field strength because of the space charge generated by the slow moving charged particles. Other factors, however, were also influenced by the presence of the dust. The effective resistance of the air gap between electrodes for example, may be reduced depending upon the conductivity of the dust. This in turn would alter the current, usually reducing it and thus reducing the field strength. If the dust is extremely fine such as in a fume, even small concentrations have a profound effect and can almost totally extinguish the corona current. This will in turn substantially reduce the precipitation performance.

The field strength in a layer of dust deposited on the plate has been calculated by Sproull and Nakada.[8] This is a function of the conductivity of the dusts. In the presence of a high-resistivity dust, the field strength may be altered considerably. This investigation, however, concerned itself only with the discharge electrodes and grounded parallel plates, however, without the added complication of current flowing through precipitated dust. It was recognized that the field would be altered by the manne in which the current flows through a dus layer.

In a tubular precipitator, the field strength will vary along the wire depending upon the degree of loading. At the inlet, the field strength will be increased due to the dust if the current/ft of discharge wire is uniform. However, the current-limiting effect of the dust may reduce the field strength more than the increase due to the charged dust particles.

For a single point, equation 12 may be modified to apply to flat-plate units to

$$E = C_0\sqrt{\frac{2i}{k}+\frac{pLr_0}{r}} \qquad (14)$$

where C_0 is a constant depending on the geometry and the point of investigation.

The presence of finer dust particles will tend to increase the field strength as will heavier dust loadings. This effect will be more pronounced nearer the plates than it will be at the discharge electrode.

As a practical example, consider the case for a dust loading necessary to result in a 10% increase in field strength. Assume flyash having a specific gravity of 2.4, a mean particle diameter of 5 microns, and an 8-inch plate-to-plate spacing, then determine the field strength at a point 1 inch from the plate. For $p=2.8$, it would require a dust loading of 8 grains/ft^3 to result in a 10% increase in field strength. This assumes the current would remain constant under such conditions.

In actual practice, however, the presence of a dust load usually decreases the discharge current to the extent that a modification of equation 7 may be applied through most of the effective cleaning region. Fig. 14 (base on data from Table I) illustrates the actual measurement of field strength at a single point between varying conditions of dust loading. The solid line is drawn for the equation

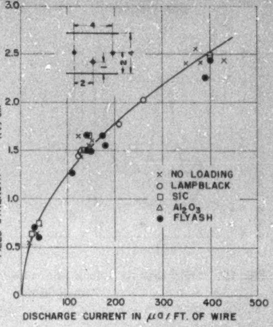

Fig. 14. Dust-loading effect on field strength in a parallel-plate precipitator, $E=0.70\sqrt{\frac{2i}{k}}$

$$E = C_0\sqrt{\frac{2i}{k}} \qquad (15)$$

where $C_0=0.70$ for the test point examined. It is evident that for all practical purposes the field strength depends more on the current than it does on the dust burden. In addition to making tests with varying degrees of dust loading, tests were made with widely differing particle size distributions and conductivity. Fig. 14 shows the field strength to be uniquely determined by the discharge current. The field strength is thus affected by the dust loading depending upon the manner in which loading affects the current. The additional effect of the charge carried by the dust was not found even at loadings as high as 20 grains/ft.^{3} It is likely, however, that for extremely fine fumes such as zinc oxide for example, the space charge carried by the dust may alter the field strength to a greater extent than indicated by current alone. For most commercial dust loadings, however, the presence of dust in the gas will vary the field strength only as it affects the discharge current.

Effect of Particle Size

The effect of particle size depends upon the area-to-weight ratio of the various size fractions. The surface area of each dust fraction is proportional to the weight of the dust fraction and inversely proportional to the square of its radius. Thus, the surface area present on 1.0 micron particles is equivalent to the area of 100 times as much dust by weight of 10 micron particles. The total effect of dust whose weight is negligible in the over-all dust burden. This may seriously affect or impair precipitator performance because of the accompanying space-charge effects.

The presence of the dust in a precipitator gas stream can be looked upon in two ways. It decreases the effective resistance of the gas separating the two electrodes and thus leads to increased current by making a more conducting path. In an extreme case, this can lead to the short-circuiting of the entire precipitator.

Second, the presence of the relatively slow moving space charge created by ions attaching themselves to the particulate matter, results in a field which is acting so as to impede the further flow of current. For a very fine nonconducting power it is possible to reduce the total current to a mere fraction of the original total current.

Formulas in this article are given in electrostatic units. Practical units are used in the curves and figures, however, for convenience.

Conclusions

1. Field-strength patterns may be determined using a dropping sphere technique in air and in a dust-laden atmosphere.

2. Field-strength patterns in a parallel-plate precipitator section indicate that increasing the discharge current increases the field strength between electrodes whereas the field directly between wire and plates is substantially unchanged.

3. An unusually high field-strength region has been found to exist in the region between discharge electrodes and is attributed to space charge.

4. The effect of wire-to-wire spacing has substantially little effect on the current-flowing per-unit plate area but the current voltage characteristics become steeper for the smaller wire-to-wire spacings.

5. A higher over-all field strength is possible with reduced wire spacing because the dips in field strength between wires are reduced.

6. The presence of dust loading in a precipitator will change the field strength as it affects the discharge current. When theory indicates surface area of the dust is a significant factor in the field-strength distribution in a precipitator, experimental data indicate that the significant factor is the total discharge current.

Automatic Regulators with Self-Balancing Magnetic Amplifiers

W. A. GEYGER
MEMBER AIEE

Synopsis: This paper is concerned with the application of the self-balancing magnetic-amplifier technique in the realm of automatic regulators. It describes two typical examples of such arrangements: 1. A constant-voltage regulator with smoothed low-impedance d-c output to be used for charging of special types of storage batteries, and 2. a constant-light-intensity regulator with a barrier-layer-type photoelectric cell for instrumentation. Both regulators employ self-balancing magnetic amplifiers with infinite internal gain and have excellent performance characteristics with regard to the respective control problems. The paper includes some considerations on the associated constant-voltage and constant-current reference circuits.

IN SELF-BALANCING magnetic amplifiers[1–3] with infinite internal gain, "critical regeneration," the output-input characteristic is defined by the resistance values of the negative-feedback channel and is not substantially influenced by changes in magnitude and frequency of the power-supply voltage, large variations in load resistance, etc. If the input voltage or input current is constant, then the output voltage or output current is constant. In this case, the self-balancing magnetic amplifier acts as a high-performance automatic regulator, the output-input characteristic (voltage ratio, current ratio, transconductance, or transresistance, respectively) of which is solely determined by actual values of resistance components. As a result of the large amount of negative electric feedback, resistance coupled into the control-circuit loop, this type of regulator has excellent performance characteristics with regard to various control problems.

This paper describes two typical examples of automatic regulators with self-balancing magnetic amplifiers: 1. A constant-voltage regulator with smoothed low-impedance d-c output to be used for charging of special types of storage batteries, and 2. a constant-light-intensity regulator with a barrier-layer-type photoelectric cell for instrumentation. Because actual performance of such arrangements depends upon that of the associated constant-voltage or constant-current reference circuit, respectively, the paper includes some considerations on such circuits.

Constant-Voltage Regulator With Smoothed Low-Impedance D-C Output (Battery Charger)

GENERAL

Some early applications of saturable-reactor devices were concerned with charging of storage batteries under automatically controlled operating conditions.[4] Rated values of output voltage and output current may be varied within wide limits, in accordance with actual requirements. When smoothed d-c output is desired, it is generally possible to apply *L-C* filter circuits in the usual way.

Development of standard-voltage or

Paper 59-174, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 27, 1958; made available for printing December 9, 1958.

W. A. GEYGER is with the United States Naval Ordnance Laboratory, Silver Spring, Md.

The author would like to express thanks to Edward T. Hooper for his helpful co-operation in conducting the oscillographic investigations. Indebtedness is also acknowledged to Walter P. Christoph and Herbert B. Reed for their help and valuable suggestions during the course of the research leading to this paper.

standard-current circuitry for automatic regulators has taken two courses. The first involves the application of a voltage discriminator, i.e., a voltage-sensitive auxiliary circuit, for example, in the form of a Wheatstone-bridge network with two linear resistors and two nonlinear resistors (e.g., metal-filament lamps). This bridge network is balanced if the regulated voltage has its rated value. Otherwise, this bridge network is thrown out of balance and produces a polarity reversible output current, which corresponds in its magnitude and direction to actual deviation of the regulated voltage from its rated value. Of course, other types of nonlinear impedance networks may be used equally well for this purpose.

The second approach consists in comparing actual value of the regulated voltage with a standard voltage which is derived from a constant-voltage reference device. There are various possibilities for comparing these two voltages in a voltage-type or current-type differential circuit. In this case, too, the resultant polarity-reversible output current corresponds with regard to its magnitude and direction to actual deviation of the regulated voltage from its rated value. This approach based upon application of a constant-voltage reference circuit has been used in the arrangement described in the following sections.

The Specific Problem

It is common practice to operate magnetic-amplifier-controlled metal-rectifier equipment for charging of lead-acid storage batteries in such a way that the voltage is maintained at 2.15–2.18 volts per cell, and so that the rectifier normally supplies the load current and the battery draws only a small current sufficient to maintain the charged condition.[5] Because in this case, the battery supplies current only if the load requirements are in excess of the rated rectifier output or if a failure of the a-c power supply occurs, the life of the battery is exceptionally long.[6]

An actual problem consisted of providing a magnetic-amplifier voltage regulator with smoothed low-impedance d-c output to charge a special type of storage battery, either single-celled or with several cells in parallel connection. The requirements were a rated value of output voltage of 1.12 volts and a regulation accuracy of ±2% for load-current variations from no-load to full-load conditions (from 0–4 amperes), for ±10% voltage variations of the frequency-regulated 60-cycle power supply.

In conventional forms of automatic voltage regulators with magnetic-amplifier circuits, *L-C* filters are successfully employed for reducing the ripple voltage, i.e., the a c component of the d-c output voltage, to sufficiently small values. However, in the present problem, application of such filter circuits for reducing the a-c component of the highly nonsinusoidal magnetic-amplifier output voltage is practically impossible for very low values of load-circuit resistance (about 0.3 ohm with full-load-current conditions).

The main difficulty of the problem is that the waveshape of the output voltage of a high-gain magnetic amplifier using rectangular hysteresis loop core material is generally a truncated sine wave which consists of a fundamental component and an array of harmonics having relatively large magnitudes. Thus, very effective filter circuits are necessary to reduce the large a-c components of the magnetic-amplifier output voltage to sufficiently small values.

The specific problem, as outlined in the foregoing, has been solved by introducing an ordinary saturable reactor operating with rectangular-hysteresis-loop core material under forced-magnetization conditions[7,8] acting as a low-gain square-wave circuit (waveform converter) between a high-gain self-balancing magnetic amplifier and the load circuit. In this way, the essential difficulty of filtering highly distorted unidirectional output voltages has been removed, because application of a full-wave-rectified square-wave output voltage minimizes the requirements on filter components. Indeed, the artifice of employing an additional saturable-reactor circuit acting as a waveform converter has proved to be of decisive importance with regard to the solution of the problem. This approach, of course, may also be attractive in other cases, where it is desirable to reduce the a-c components of the output voltage and to minimize requirements on filter components.

Application of a self-balancing magnetic amplifier with infinite internal gain offers various advantages concerning the performance characteristics of automatic voltage regulators. However, because these amplifiers operate in principle under natural-magnetization conditions[7,8] the output-voltage waveshape corresponding to that of conventional forms of high-gain self-saturating circuits is highly distorted. For this reason, the artifice of introducing an additional saturable reactor circuit acting as a waveform converter is of particular importance. In this way it is possible to combine the specific advantages of both types of magnetic-amplifier circuits (high gain of self-balancing magnetic amplifiers, and square wave output of ordinary saturable reactors operating under forced-magnetization conditions) to obtain optimum performance.

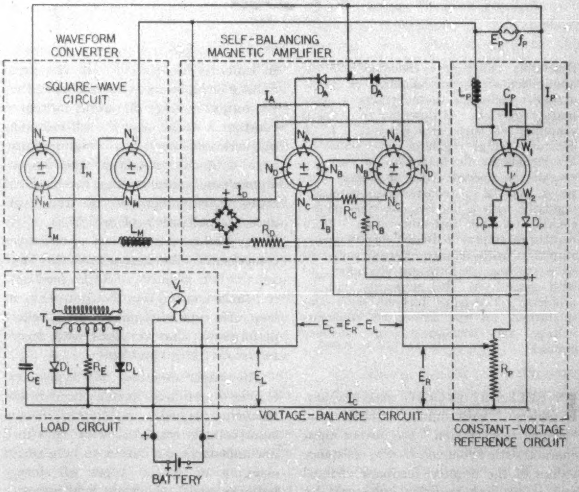

Fig. 1. Circuit diagram of the constant-voltage regulator (battery charger) with a self-balancing magnetic amplifier operating under voltage-balance conditions

THE REGULATOR CIRCUIT[7]

Fig. 1 shows a circuit diagram of the automatic voltage regulator, which has four main parts: 1. The constant-voltage reference circuit providing the constant reference voltage E_R. 2. The load circuit applying to the storage battery (or some other d-c load) the load voltage E_L to be regulated to have a constant value. 3. A self-balancing magnetic amplifier with the voltage-balance circuit (resultant control voltage $E_C=E_R-E_L$) and a full-wave rectifier in the output circuit. 4. An ordinary saturable reactor with smoothed control current I_M (choke coil L_M) acting as a waveform converter and producing the square-wave output current I_N).

The magnetic voltage stabilizer of the constant-voltage reference circuit is a parallel-type ferroresonant network consisting of a nonlinear reactor T_P with rectangular magnetic characteristic (Orthonol 2-mil tape core) and two separate center-tapped toroidal windings W_1, W_2, a capacitor C_P, and a linear reactor L_P with Permalloy-dust core. Potentiometer resistor R_P is supplied from a full-wave rectifier circuit with two silicon diodes D_P and permits adjustment of the reference voltage E_R to the desired value, e.g., 1.12 volts.

The self-balancing magnetic amplifier comparing actual magnitudes of the control-voltage components E_R and E_L has the following parts: 1. The self-saturating circuit with Orthonol 2-mil tape cores, gate windings N_A and series-connected silicon diodes D_A. 2. The bias circuit with d-c bias windings N_B and series resistor R_B provided for adjusting the operating point of the self-saturating circuit, i.e., actual magnitude of the quiescent current (output current I_A with no-signal conditions). 3. the d-c control windings N_C (resistance R_C) carrying the control-winding current I_C, which is substantially reduced to zero. 4. The d-c positive-feedback windings N_D with regeneration-control resistor R_D for adjustment of critical regeneration (infinite internal gain of the amplifier).

The waveform converter consisting of an ordinary saturable reactor with Orthonol 2-mil tape cores, series-opposing connected a-c load windings N_L, series-aiding-connected d-c control windings N_C and choke coil L_M is characterized by the fact that its d-c control circuit represents a very high impedance with regard to even harmonic currents. Thus, the saturable-reactor elements operate under forced-magnetization conditions[7,8] i.e., the alternating output current I_N has a nearly reactangular waveshape.

The load circuit converting the alternating square-wave current I_N into a smoothed unidirectional output current contains the following components: 1. The output transformer T_L with center-tapped secondary winding. It acts as a step down transformer (voltage ratio 60/(3+3) volts) and provides the necessary insulation between the a-c power supply (voltage $E_P=120$ volts ±10%, frequency $f_P=60$ cps) and the control-circuit components. 2. Two silicon diodes D_L providing full-wave rectification. 3. An internal load resistor $R_E=1$ ohm, which limits the output-current range of the regulator to a minimum value of about 1 ampere. Thus, even if the external load current drawn by the battery or some other d-c load is reduced to zero, the saturable-reactor square-wave circuit is still loaded by the constant internal load current flowing through the 1-ohm resistor R_E. 4. A 4,000-microfarad smoothing capacitor C_E, which substantially removes the remaining sharp-pulse a-c components of the full-wave-rectified load voltage E_L. 5. A moving-coil voltmeter V_L for indicating or recording of actual magnitude of the d-c load voltage E_L.

PRINCIPLE OF OPERATION AND PERFORMANCE CHARACTERISTICS

When drawing no external load current from the output terminals of the regulator, the magnitude of the output current is solely determined by the 1-ohm resistor R_E and the parallel-connected high-impedance voltmeter V_L. In accordance with the basic principle of voltage-balance-type self-balancing magnetic amplifiers with infinite internal gain, the reference voltage E_R (representing the signal voltage) is balanced by the load voltage E_L (representing the compensating voltage), and, with critical regeneration of the amplifier, the current flowing in the control-circuit loop is substantially reduced to zero. If this case, the internal output current of the 1-ohm resistor with voltmeter V_L is controlled by an infinitesimal d-c flux increment in the cores of the self-saturating circuit. It is to be noted that the balance conditions are not substantially influenced by changes of the characteristics of the amplifier components, fluctuations of the 60-cycle power-supply voltage E_P, et cet.

If now an external load resistor, e.g., a discharged storage battery, is suddenly connected with the output terminals of the regulator, an external load current is drawn, which increases the voltage drops across the secondary winding of transformer T_L and the rectifier elements D_L. As a result, during the transient operation of the regulator, the load voltage E_L drops in a certain amount, i.e., $E_L<E_R$, and a resultant control voltage $E_C=E_R-E_L$ of positive direction causes alternating output current I_A, smoothed unidirectional control current I_M, square-wave current I_N, and the d-c output voltage E_L to increase in such an amount that balance conditions are restored. On the other hand, if the external load current is suddenly reduced, then $E_L>E_R$, and a resultant control voltage $E_C=E_R-E_L$ of negative direction will cause currents I_A, I_M, I_N, and voltage E_L to decrease in such an amount that balance conditions are restored again.

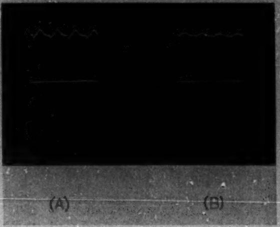

Fig. 2. Oscillograms of the waveform of the output voltage E_L of the constant-voltage regulator of Fig. 1

A—Without smoothing capacitor C_E
B—With a 4,000-microfarad capacitor C_E

A breadboard model of a 5-watt regulator corresponding to the circuit diagram of Fig. 1 has been investigated with regard to waveform of the output voltage, influence of load-current variations on actual magnitude of output voltage, and transient response.

The oscillograms of Fig. 2 show the waveform of output voltage E_L with full output for the following operating conditions: 1. The 4,000-microfarad electrolytic capacitor C_E is disconnected, and 2. this capacitor is parallel-connected to the output terminals, as shown in Fig. 1, to remove the remaining sharp-pulse a-c components of E_L. The ratio between peak value and average value of E_L is dependent on the magnitude of load current (0–4 amperes) and varies within the range of from 1.05–1.1.

In order to determine the influence of variations of load current I_L on actual magnitude of load voltage E_L, a variable resistor (0–100 ohms) has been connected in series with a moving-coil ammeter across the output terminals of the regulator; and a high-precision d-c potentiometer circuit has been employed for measuring the very small changes in magnitude of the output voltage E_L. The perform-

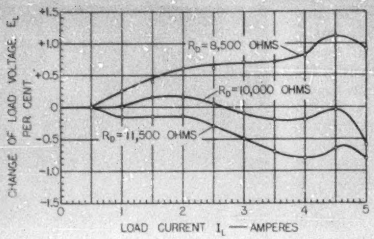

Fig. 3. Results of measurements on the constant-voltage regulator of Fig. 1: percentage change of output voltage E_L as a function of output current I_L with regeneration-control resistance R_D as a parameter

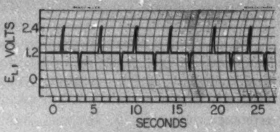

Fig. 4. Brush-recorder ink oscillogram characterizing the transient response of the constant-voltage regulator of Fig. 1

ance characteristics of Fig. 3 show the percentage change of E_L as a function of I_L with regeneration-control resistance R_D (Fig. 1) as a parameter. Evidently, with optimum adjustment (R_D=10,000 ohms), output voltage E_L varies within the limits of about ±0.2% in the entire range of load current I_L.

The transient response of the regulator has been measured by means of a magnetic-amplifier-operated ink oscillograph (Brush recorder).[9] The voltage (E_L) to be investigated is of the order of 1 volt, whereas the operating voltage of the Brush recorder is about 20 volts for full-scale deflection of the ink pen. Thus, the voltage gain (about 20) of the self-balancing magnetic amplifier operating the recorder has been adjusted so that E_L=1.0 volt corresponds to 80% of full-scale deflection (40 scale divisions) of the recorder.

Transient performance of the regulator has been tested by means of manually operated switch which connects and disconnects alternately a 0.3-ohm load resistor across the output terminals (output current I_L=4 amperes or zero, respectively). The test procedure consists in closing and opening the switch six times during a period of about 25 seconds. The corresponding oscillogram, Fig. 4, shows that, when closing the switch (I_L changes suddenly from 0–4 amperes), the output voltage E_L at first drops from its rated value of 1.2 volts to 0.4 volt and then, within about 0.5 second, reassumes the rated value. On the other hand, when opening the switch (I_L changes suddenly from 4 amperes to zero), E_L at first jumps from 1.2 volts up to 2.6 volts and then, within about 0.5 second, reassumes its rated value. In any case, after a small overshoot, the balance condition is restored. It is to be noted that, in the present problem (charging of storage batteries), the transient performance of the regulator has minor importance, because the load current I_L changes slowly during the charging procedure.

Referring to the performance characteristics of the simple constant-voltage reference circuit, as shown in Fig. 1, it is to be noted that in the specific problem outlined in a previous section of this paper, a regulation accuracy of ±2% was required at room temperatures for ±10% variations of the frequency-regulated 60-cycle power supply. With these moderate requirements, the accuracy of regulation of this form of constant-voltage reference circuit (about ±1% or better) has proved to be sufficient, and application of some frequency-compensating circuit has been considered not to be necessary in this case.

Constant-Light-Intensity Regulator for Instrumentation

General

Saturable-reactor-type constant-voltage regulators have been used successfully for eliminating those changes in light intensity of metal-filament lamps, which are caused by voltage fluctuations of the a-c power supply. This method of regulation, of course, involves the basic assumption that the performance characteristics of the lamp to be regulated, i.e., the properties of its metal filament, remain unchanged over long periods of time. Actually, however, as a result of "aging" effects, the relationship between applied voltage and light intensity changes considerably when operating a metal filament lamp with its rated value of voltage.

An improved method for constant-light-intensity regulation consists in applying a magnetic-amplifier regulator in conjunction with a barrier-layer-type photoelectric cell in such a way that the regulation is inherently independent of aging of the lamp.

In this case, the automatic regulator (besides its usual performance) takes care of the changes in performance characteristics of the lamp. That is, within certain limits, the regulator, automatically and continuously, also eliminates those effects, which are caused by changes of the relationship between light intensity and applied voltage or applied current, respectively.

The Specific Problem

In an actual case, the problem consisted of providing an area of constant light intensity (constancy: ±1%) for instrumentation. A conventional-type low-voltage lamp (rated voltage 5 volts, corresponding filament current about 2 amperes) is to be used in such a way that changes in performance of the lamp caused by aging will have no appreciable effect on the ±1% accuracy of regulation.

The general approach was to employ a magnetic-amplifier regulator in conjunction with a barrrier-layer-type photoelectric cell in such a way that the output current of this cell is constant within the limits of ±1%. It was considered to be permissible to apply here the basic assumption that the performance characteristics of the barrier-layer-type photoelectric cell remain unchanged, i.e., the relationship between light intensity and photoelectric output current is constant within the limits of ±1% over long periods of time.

The essential part of this specific problem was characterized as follows. If a light-absorbing body, for example, a plate of glass or some similar material producing an absorption of about 10–20%, is placed between the lamp and the light-sensitive surface of the photoelectric cell, then the magnetic-amplifier regulator will automatically compensate for this absorption so that the output current of the cell remains substantially unchanged. This means that in this case, the regulator must increase the voltage applied to the lamp exactly in such an amount that the increased light intensity of the lamp does compensate for the loss of radiation produced by the light-absorbing body, which has been placed between the lamp and the cell.

Application of a self-balancing magnetic amplifier in conjunction with a high-performance barrier-layer-type photoelectric cell made a simple solution of this problem possible. This novel approach is based upon the recognition that the combination of an a-c-supplied metal-filament lamp

Vol.
Pt. 1
1959

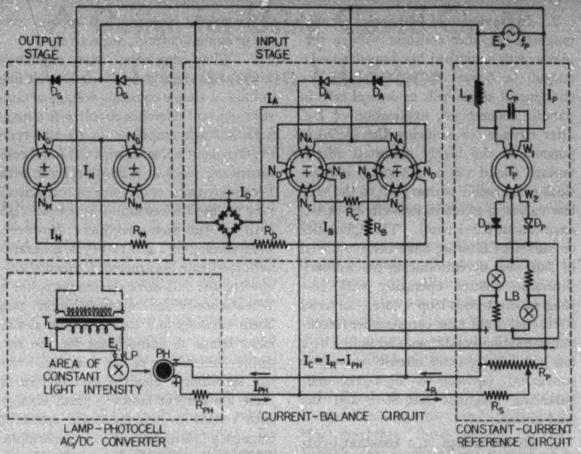

Fig. 5. Circuit diagram of the constant-light-intensity regulator with a self-balancing magnetic amplifier operating under current-balance conditions

with such a d-c producing photoelectric cell is a special form of an a-c/d-c converter, which lends itself particularly well to application with the self-balancing magnetic-amplifier technique.

In accordance with this concept, the "lamp-photocell a-c/d-c converter" is introduced into the negative-feedback channel of a self-balancing magnetic-amplifier circuit with infinite internal gain operating under current-balance conditions. This approach offers various advantages concerning performance characteristics of a constant-light-intensity regulator which automatically and continuously compensates for the effects produced by aging of the lamp to be regulated.

The Regulator Circuit

Fig. 5 shows a circuit diagram of the constant-light-intensity regulator, which has four main parts: 1. The constant-current reference circuit providing the constant reference current I_R. 2. The lamp photocell a-c/d-c converter producing a direct output current I_{PH} which is a measure for the actual light intensity influencing the photocell. 3. A self-balancing magnetic amplifier (input stage) with the current-balance circuit (resultant control current $I_C = I_R - I_{PH}$) and a full-wave rectifier in the output circuit. 4. A self-saturating magnetic amplifier (second stage) controlled by the full-wave-rectified output current I_M of the input stage and supplying a variable alternating output current I_N to the lamp-photocell a-c/d-c converter.

Because this regulator may sometimes be supplied from a small 60-cycle generator with moderate accuracy of frequency regulation, a special form of two-stage constant-current reference circuit has been employed in this case. The first stage, a magnetic voltage stabilizer (similar to that of Fig. 1) eliminates the disturbing effects of sudden changes in magnitude of power-supply voltage E_P and supplies the full-wave rectifier circuit with two silicon diodes D_P. The output voltage of this rectifier circuit, however, is linearily proportional to power-supply frequency f_P. In order to compensate for disturbing effects of variations of f_P, the constant-current reference circuit has a second stage, which consists of a Wheatstone-bridge network *LB* with two linear resistors and two nonlinear resistors (small metal-filament lamps, 6 volts, General Electric type *46*). The thermal inertia of these lamps is small enough with regard to the moderate speed of frequency variations of the a-c generator.

Additionally, the lamp-bridge network *LB* compensates for changes in voltage drops across rectifiers D_P and also for the effect of variations in ambient temperature on the saturation-flux density of the Orthonol core of the magnetic voltage stabilizer. Thus, in the 2-stage reference circuit of Fig. 5, the first stage takes care of sudden changes in magnitude of power-supply voltage, whereas the second stage performs the following three functions: 1. it compensates for the lower-speed frequency variations of the a-c generator, 2. it eliminates the effect of variations of voltage drops across the full-wave rectifier elements, and 3. it eliminates the effect of ambient temperature on the saturation-flux density of the saturating-core reactor of the magnetic voltage stabilizer of the first stage.

The self-balancing magnetic-amplifier circuit (input stage) comparing actual magnitudes of the control-current components I_R and I_{PH} is similar to that of Fig. 1. However, because the input-power level here is much smaller than that of the arrangement of Fig. 1, Supermalloy 2-mil tape cores have been used in this case.

The second stage consisting of a conventional-type self-saturating circuit with Orthonol 2-mil tape cores, gate windings N_G, d-c control windings N_M, and control-circuit series resistor R_M supplies the variable alternating current I_N to the primary winding of output transformer T_L.

The lamp-photocell a-c/d-c converter contains a 5-volt 2-ampere lamp (General Electric type *1709*) connected across the secondary winding of the step-down transformer T_L (voltage ratio 50/5 volts), and a high-performance barrier-layer-type photocell PH (Weston "Photronic Photoelectric Cell", model *856*, hermetically sealed) with series resistor R_{PH} in its output circuit.

Principle of Operation and Performance Characteristics

When placing a plate of glass or similar material producing an absorption of about 10–20% between the lamp and the light-sensitive surface of the photoelectric cell, the intensity of radiation influencing this cell is reduced. As a result, during the transient operation of the regulator, the output current I_{PH} of the cell drops in a certain amount, i.e., $I_{PH} < I_R$, and (because I_R is constant) a resultant control current $I_C = I_R - I_{PH}$ of positive direction causes alternating output current I_A of the first stage and the corresponding control current I_M of the second stage to decrease. Thus, output current I_N, lamp current I_L, lamp voltage E_L, and the light intensity influencing the photocell will increase in such an amount that balance conditions are restored. On the other hand, if the light-absorbing body is removed, then $I_{PH} > I_R$, and a resultant negative control current $I_C = I_R - I_{PH}$ will cause increasing of currents I_A, I_M, and corresponding decreasing of I_L, E_L and light intensity in such an amount that balance conditions are restored again.

A breadboard model of the constant-light-intensity regulator corresponding to the circuit diagram of Fig. 5 has been investigated with regard to accuracy of regulation and transient response, which is influenced by the properties of the regulator circuit itself and also by the thermal inertia of the lamp.

In order to simulate changes in performance characteristics of the lamp, caused by the effect of aging over longer periods of time, transparent plates of various thicknesses have been introduced between the lamp and the light-sensitive surface of the photoelectric cell. The amount of absorption varied actually in the range of about 10–20%. Larger rates of absorption have been produced by partially covering the cell by a metal plate. In any case, the magnitude of output current I_{PH} of the cell remained constant, and the accuracy of regulation was ±1% or better, when using infinite internal gain of the self-balancing magnetic-amplifier circuit. The associated variations of the rms value of lamp voltage E_L (measured with an iron-vane voltmeter) are in the range of from about 4.8–5.6 volts.

The transient performance of this regulator has been investigated by suddenly removing an absorption plate, which covers the light-sensitive surface of the cell. In this case, after a transient operation of 0.6 second balance conditions of the regulator circuit are restored. If larger variations of power-supply voltage E_P are expected, particularly with sudden changes of E_P, it is advisable to supply the regulator circuit from a conventional-type magnetic voltage stabilizer.

Conclusions

1. Application of self-balancing magnetic amplifiers with infinite internal gain ("critical regeneration") in automatic regulators, as described in this paper, offers various advantages concerning the performance characteristics of such regulators. However, it is to be noted that these amplifiers operate in principle under natural magnetization conditions. Therefore, the output-voltage waveshape corresponding to that of conventional forms of high-gain self-saturating circuits is highly distorted. In many cases it is possible to apply *L-C* filter circuits in the usual way for reducing the a-c components of the unidirectional output voltage of the amplifier to sufficiently small values.

2. In the design of a 60-cycle-operated magnetic-amplifier constant-voltage regulator with smoothed low-impedance d-c output (a 5-watt battery charger for charging of single cells or several cells in parallel connection), application of *L-C* filter circuits for reducing the a-c components of the highly distorted output voltage (rated value 1.12 volts) is practically impossible with regard to the very low values of effective load-circuit resistance (about 0.2–1 ohm). The difficulties on sufficient filtering have been removed in this case by introducing an ordinary saturable reactor operating with rectangular-hysteresis-loop core material (Orthonol 2-mil tape cores) under forced-magnetization conditions and acting as a low-gain square-wave circuit (waveform converter) between a high-gain self-balancing magnetic amplifier and the load circuit.

3. In the design of a constant-light-intensity regulator for instrumentation, a novel approach consists in applying a magnetic-amplifier regulator in conjunction with a high-performance barrier-layer-type photoelectric cell in such a way that the regulation is inherently independent of aging of the metal-filament lamp to be regulated. In this case, besides its usual performance, the regulator takes care of the changes in performance characteristics of the lamp. That is, within certain limits, the regulator automatically and continuously eliminates those disturbing effects, which are caused by changes of the relationship between light intensity and applied voltage or applied current, respectively. This approach, however, involves the basic assumption that the relationship between light intensity and output current of the photoelectric cell is constant within the limits of ±1% over long periods of time.

4. The transient performance of both regulators, as described in this paper, may be described by a time constant of about 0.4–0.6 second. Although the principle of operation of these regulators includes elimination of the effects of changes in magnitude of the 60-cycle power-supply voltage, it may be advisable in some cases to supply the regulator circuit from a conventional-type magnetic voltage stabilizer to eliminate the effects of sudden larger changes of the power-supply voltage. It is to be noted that the main purpose of these regulators is to eliminate the effects of changes arising in the regulator circuit itself, e.g., variable voltage drops across transformer windings and rectifier elements, and changing of the performance of metal-filament lamps as a result of aging, i.e., changes of the relationship between light intensity and applied voltage or applied current, respectively.

5. When supplying these regulators from the frequency-regulated 60-cycle line voltage, a simple constant-voltage or constant-current reference circuit with a magnetic voltage stabilizer (a parallel-type ferroresonant network with Orthonol-core saturating reactor, a linear reactor with Permalloy-dust core, and a capacitor) may be used successfully in conjunction with a full-wave rectifier. However, when employing a small 60-cycle generator with moderate accuracy of frequency regulation, the full-wave rectifier supplies a Wheatstone-bridge network with two linear resistors and two small metal-filament lamps to compensate for the frequency sensitivity of the magnetic voltage stabilizer. The thermal inertia of these low-current lamps is small enough with regard to the moderate speed of frequency variations of a-c generators. Additionally, the lamp-bridge network compensates for changes of voltage drops across the full-wave rectifier elements. Thus, in this simple form of a two-stage constant-voltage or constant-current reference circuit, the first (magnetic-core) stage takes care of sudden changes in magnitude of the power-supply voltage, while the second (lamp-bridge) stage compensates for the low-speed frequency variations of the a-c power supply and also eliminates the effects of variations of voltage drops across the full-wave rectifier elements and the effect of ambient temperature on the saturation-flux density of the Orthonol core of the magnetic voltage stabilizer.

A Design for Using Closed-Circuit Television in Education

FRANCIS E. ALMSTEAD
NONMEMBER AIEE

THE TELEVISION medium cannot be used to solve all problems in the field of education. Its value as a means of communication for sight and sound will be as good as the quality of imagination and management which directs its utilization. Those who have professional courage can use its strength to improve and extend education. An increase in school population, increase in school costs and a growing shortage of experienced teachers are some of the rapid changes taking place in the field of education today. We all recognize that satisfactory solutions to each of these problems must be found in order to provide the quality education for our children which our society demands.

The American public has made considerable progress by building more schools and increasing teachers' salaries, but there is more to be done in providing equal educational opportunities for all youth and in upgradng the quality of education generally. School boards and professional educators are looking for new methods and devices which will help teachers meet their responsibility and which will create better learning conditions. With the rapid growth of technology during the past decade, it is natural for them to turn to electronics.

The Regents of the University of the State of New York recognized in electronic devices a potential for education and, in 1951, began to encourage the investigation and the use of television in education. Today, the New York State Education Department, under James E. Allen, Jr., Commissioner of Education, is conducting a very extensive investigation in all phases of this medium. Its four experiments in broadcast and closed-circuit television embrace many techniques and technical arrangements. One, a broadcast project, began on September 22, 1958, over channel 11 in New York City. These broadcasts can be viewed in four states, 8 hours a day, Monday through Friday. The viewing area in New York State has a million and a half public school children. In the Regents' broadcasting schedule there are six elementary grade subjects and six secondary school courses. Each of these follows a regular approved State syllabus.

Two other experiments are located in State University Teachers Colleges in Brockport and Albany where closed-circuit facilities are used from grade three through college. These systems use video distribution and a separate 2-way audio circuit. The facilities are within a single building at each college.

In Cortland County, the department is experimenting with closed-circuit facilities involving three school districts. Schools are connected by coaxial cable and use an independent pupil talkback system. In four locations, these facilities are financed by State appropriations and give the department the greatest undertaking ever attempted in educational communications by one institution.

The story of this latter system is told in three papers. This paper introduces the general aspects of the system and its basic educational requirements. A paper by Wall will discuss the technical aspects of the coaxial cable system.[1] A paper by Norton and Davidson will describe the design and operation of the independent talkback system which has never been attempted before on such a large scale.[2]

Educational Objective

In the rolling and hilly land of Cortland County, New York, educational television connects three school systems, one in a city and the other two in villages (Fig. 1). These are directed by two superintendents and three Boards of Education. Involved are the city of Cortland and the villages of Truxton and Virgil. Truxton is 9 miles and Virgil is 6 miles from the city of Cortland. Dr. Franklyn Barry, Superintendent of Schools in the city of Cortland, and Chester Lacey, District Superintendent, working in close cooperation with faculty members, proposed a plan whereby the three school systems could exchange benefits with each other through closed-circuit television. This plan incorporated four basic questions on the use of television facilities:

1. Can pupils in small schools have the advantages of services usually found only in large schools?
2. Can teaching talent be extended successfully into more than one classroom at a time?
3. Can the level of learning be raised?
4. Can schools provide courses which are now prohibited by excessive cost?

In the city of Cortland, there are about 4,500 pupils housed in five elementary schools and one junior-senior high school. In Truxton Central School there are 600 pupils in classes from kindergarten through the 12th grade. In Virgil Central School there are 400 pupils in these grades. By committee action it was decided to equip all second and fifth grade rooms in the elementary schools and a number of high school rooms in the three systems with television receivers. It was further decided to teach science to elementary school grades and basic art, English, health and mathematics to high school pupils. Teaching schedules began on September 29, 1958.

System Design Requirements

This system offers great promise and already has aroused much interest because of its uniqueness. Its electronic circuitry was planned through joint action by Dage (a Division of Thompson Products), Master Video Systems, the New York Telephone Company, and the New York State Education Department. To serve as headquarters for the project, and to house the studios, the city of Cortland Board of Education released a 2-room elementary school building, no longer in use (Fig. 2). The Board has refurbished the building. While origination may take place at any of the six Cortland schools, teaching will be done in the modern studios at the erstwhile "little red school house." Studios, control rooms, and classrooms have been equipped with electronic and television items by the State Education Department. Radio-frequency distribution and independent talkback systems have been installed by the New York Telephone Company and are being rented by the Department. The total system was planned with specific operating conditions in mind, some of which are:

1. Pupils should be able to see in full detail all of the intelligence transmitted by the television cameras without distraction or distortion.

Paper 59-194, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted October 20, 1958; made available for printing December 23, 1958.

FRANCIS E. ALMSTEAD is with the New York State Education Department, Albany, N. Y.

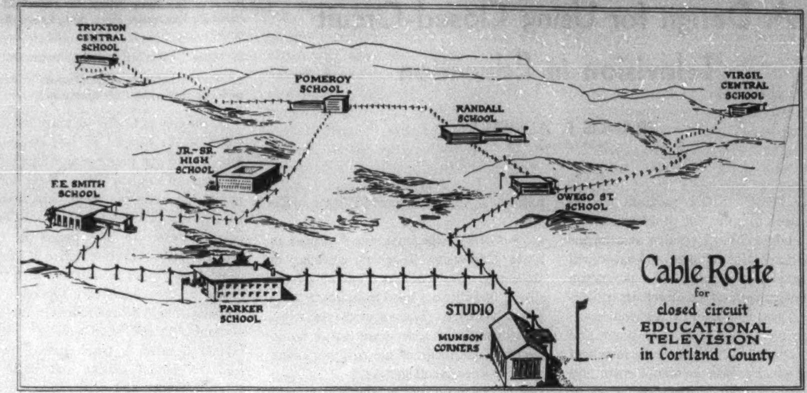

Fig. 1. System layout

2. Camera chains should be capable of faithfully reproducing the full intelligence in a picture, microscopic slide, printed matter, movie or transparency.

3. Natural atmosphere of a classroom should be retained in the viewing room.

4. Pupils should be able to hear all sounds without distortion, distraction, discomfort, or undue effort.

5. Pupils should be able to ask questions and receive immediate answers from the studio teacher.

6. System should be designed as an educational communications center capable of serving the entire school community with live lessons, motion pictures, slides, special programs and demonstrations, stereophonic recordings and 2-way audio programs.

7. System should permit separate transmissions to elementary and secondary schools simultaneously.

To meet these objectives two fully equipped studios and two radio-frequency channels have been provided. In addition, adequate distribution systems within each school, including high quality receivers, have been installed.

Studio Design and Equipment

Two studios are located in the converted 2-room school house. Design follows that used for commercial studios. Windows have been sealed, the walls have been treated with fiber glass held in place by chicken wire and covered with draped monk's cloth, a grid work of pipes for mounting lights has been hung from the ceiling, and independent electrical outlets have been placed systematically in the ceiling. Each outlet is controlled by a switch in the studio's control room. Lights can be operated independently, and the intensity of each light can be controlled by a dimmer. Thus, it is possible to obtain balanced light for any setting. A green chalk board with pin up boards on each end has been mounted on the wall facing the cameras. In order to obtain backlighting on the teacher and to reduce reflections from the board, it is held out from the wall with its upper edge extending forward from the vertical.

One of the studios is equipped with two professional Vidicon camera chains (Fig. 3). These are capable of fine quality performance with 600-line definition. The other studio is equipped with two other Vidicon camera chains which are capable of 500-line definition (Fig. 4). Two kinds of cameras were installed so that relative operational characteristics could be studied.

There is also a film chain suitable for showing 16-millimeter motion pictures and 35-millimeter slides and filmstrips (Fig. 5). It can be run independently or it can be used to support a teacher's presentation from the studio.

Chains operate through a console in the studio's control room (Fig. 6). From here the video and audio signals are transmitted to separate amplifiers in the

Fig. 2 (left). Studio building

Fig. 3 (right). A 600-line Vidicon camera

Fig. 4 (left). A 500-line Vidicon camera

Fig. 5 (right). Film chain

basement. Output from each video amplifier is a 1-volt, peak-to-peak, standard television signal. Quality control is essential, for unless the camera chains and audio equipment are operating at peak performance, it is impossible for the receivers to reproduce all of the intelligence the teacher hopes to convey. It is important to know the quality of the signal from the camera as well as the output from the video amplifiers. Thus, two *A* scopes (Fig. 7) are used in the control rooms for comparing camera output with video amplifier output. Change in signal composition can be observed immediately. Again for quality operation of the system, it is essential that the radio-frequency carrier be properly modulated all the time. A video-limiter amplifier is used to prevent overmodulation.

A good quality audio signal at 0 volume units across 600 ohms is supplied to the transmitter from either studio through an automatic gain control amplifier. This signal is monitored in the control room.

Studio lighting depends on the characteristics of the television pick-up tube. The Vidicon, for instance, requires more light than the image orthicon, but its nearly constant gamma characteristic permits a picture with tonal qualities approximating good photographs. In order to obtain this quality the incident light in a studio should be at least 200 foot-candles. The iris opening of the lens should be at f2.8. If 400 foot-candles of incident light are used, the iris may be reduced to f4.0. In both studios at Cortland up to 500 foot-candles of incident light are available. Full illumination is seldom used because of the excessive heat generated. It is, nevertheless, necessary to have reserve light to illuminate large areas or objects of small reflection.

Coaxial Cable Route

The coaxial cable route in Cortland is about 9 miles, the extension to Virgil is 6 miles, and to Truxton, about 11 miles. Situations representing various distances were chosen so that a cost analysis based on mileage and pupils served could be made. It seems logical to believe that a long cable to serve few pupils may not be practical. We hope to determine from experience with this installation the number of pupils required per mile of cable for an economically feasible operation.

Classroom Equipment and Utilization

Classrooms are equipped with two 24-inch or 21-inch table model receivers (to be modified by the addition of a quality speaker placed in front and below the set). The system of distribution in each school is designed to supply a minimum of 1,000 microvolts to each receiver. Each room has three 5-inch speakers serving the talkback system (Fig. 8). These

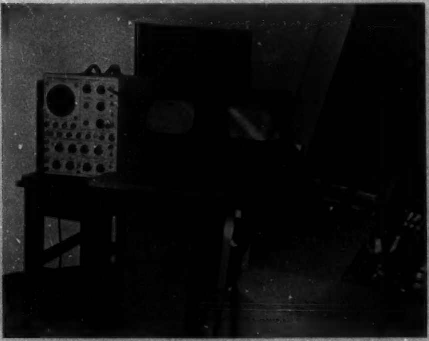

Fig. 6. Control room equipment

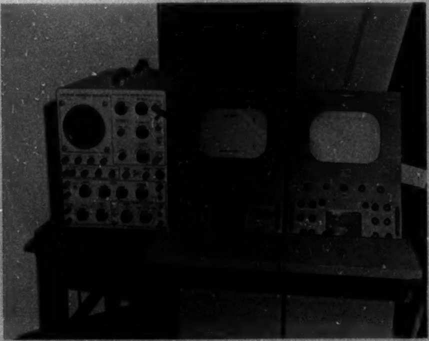

Fig. 7. Auxiliary "A" scope and monitors

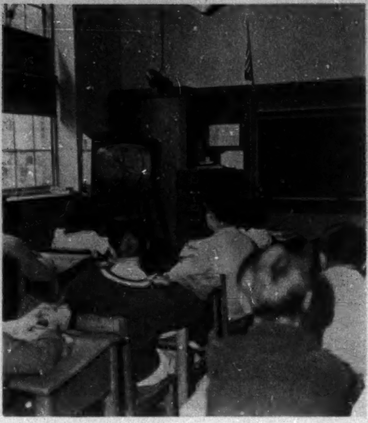

Fig. 8. Typical viewing and talkback equipment

speakers are used also as microphones and are suspended from the ceiling.

The talkback system is an important feature in the project. When used the pupil may talk to the teacher or the teacher may seek an answer from a pupil. Through the use of switches and signal lights the circuit can serve either the pupil or teacher. Pupils are not required to leave their seats when asking a question or giving an answer. Pupils in all other classrooms associated with the studio, as well as the studio teacher, will hear the child's voice clearly and without distortion. This system gives pupils the feeling of belonging and security through participation.

It is essential for all equipment from cameras in studios to receivers in classrooms to operate at peak performance at all times. Without excellent picture and sound quality throughout the system, transmission of intelligence will be substandard. This cannot be tolerated. It is, therefore, important for the project to have a full-time, well-qualified electronics technician. He has responsibility for the maintenance of all studio equipment and all television receivers at the schools. Experience may demonstrate the need for two technicians, one to concentrate on studio equipment, the other on receiver maintenance.

It is important that the televised lessons coming to the classrooms be of high quality, appropriate, and timely to learning (Fig. 9). It is of equal importance to create in the classrooms proper conditions and atmosphere (Fig. 10). Too many pupils viewing at one receiver, too great a distance between viewers and set, improper picture contrast and brightness, poor sound and poor picture definition will be deterrents to effective learning. Ideally, receivers, tipped slightly forward at the top, should be placed on stands in a room so that window glare does not interfere with the pupils' vision and so that the center of the picture is slightly above eye level of the viewing group (Fig. 8). It is also important for pupils to have those materials and supplies necessary to enable them to participate fully in the televised lesson. It is the responsibility of each teacher to make certain that classroom and receiver conditions are proper for maximum learning (Fig. 11).

Television Receivers

A television receiver when placed in a classroom has a role different from that which it plays in the home. A home viewing is casual and generally done for entertainment, while in the classroom it is the means of communicating intelligence to viewing pupils. Therefore, the circuitry of the receiver must reproduce the input message with a minimum of degradation. Design and performance of the set must be of high quality.

Experience has found the following technical considerations to be of great importance:

1. Ninety-degree picture tube, which gives better focus and less distortion than the 110-degree tube.
2. High-voltage power supply with an output of 18 kv, in no case less than 16 kv.
3. Variation in voltage greater than 2 kv between maximum and minimum brightness control adjustment.
4. Isolated chassis and a transformer power supply with heaters in parallel.
5. Adjustable keyed automatic gain control.
6. In the intermediate-frequency video section a band width of 4.5 megacycles and

Vol
Pt.
19

Fig. 9. Teacher in studio

Fig. 10. Typical classroom arrangement

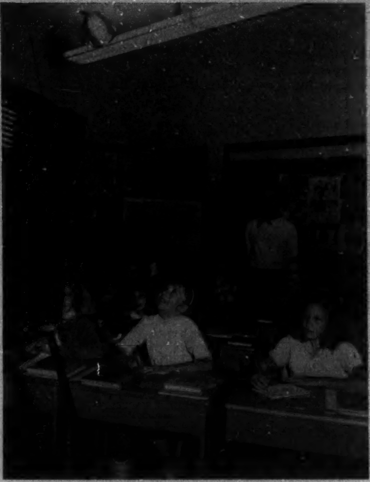

Fig. 11. Teacher in classroom

in the video amplifier a band width of 3.5 megacycles. These conditions make possible 300-line definition in the picture readable from a standard test pattern.

7. Brightness control range from black to 60 volts above cutoff.

8. Sensitivity range for lower channels at least 20 microvolts and for higher channels at least 40 microvolts to produce a 20-volt peak-to-peak input to the picture tube.

9. Audio amplifier with 5 watts of undistorted output.

10. Full range response speaker, 80 to 13,000 cycles, flat to ±3 db, baffled properly and mounted at the front.

Methods of Utilization

SIMULTANEOUS INSTRUCTION OF SMALL GROUPS

In communities where cost of education has become a burden, it may be impossible for boards of education to employ teachers for specialized work such as teaching of foreign languages, music, art, and science in elementary schools. A closed-circuit cable system like that installed in Cortland County provides a means by which boards of education may join together to employ an outstandingly well qualified person to teach each subject. A program for shared educational services over a cable system is working very well in Cortland county. Science taught by a studio teacher is available to all fifth grade pupils in the three school districts. Music is available this year for the first time to seventh and eighth grade pupils at Truxton and Virgil and is taught by a music teacher from the city of Cortland Board of Education.

USE BY INEXPERIENCED TEACHERS

In the upper grades particularly, inexperienced teachers need help in developing excellence of performance and competency in subject matter. While a new teacher is growing professionally, some pupils may be handicapped through inadequate teaching. This damage to learning can be avoided by the use of a television cable system which makes it possible for an experienced teacher to present authentic subject matter and skillful demonstrations to pupils wherever they are at one time. The teacher in the viewing room is responsible for pupil success. He has an opportunity to work with his pupils during two periods a week. In the case of high school physics, for example, the classroom teacher may use one of these periods for laboratory exercises and the other for drill, problem solving and examinations.

This team relation assures excellence of performance for all pupils and offers an opportunity to a new teacher for professional growth.

SPECIAL SUBJECT MATTER

In almost every school there are a few pupils who have exceptional ability. Schools, especially the smaller ones, are not able financially to employ a diversified staff to satisfy the needs of their gifted pupils. In several schools connected by cable there will be a sufficient number of superior boys and girls to justify the employment of proper faculty to serve the group.

TOTAL TEACHING

In certain situations, pupils in small groups can be taught effectively by a studio teacher having complete charge of the conduct of the course. Viewing rooms need not be supervised by qualified subject matter teachers. In some cases, teacher aides have been assigned to viewing rooms and in others a classroom chairman has been found to be satisfactory. To make this system effective the studio teacher and pupils need the advantages of 2-way audio communication. The advantages of this system are clear: Pupils may ask to have a point clarified or the teacher may ask a pupil to recite. All pupils, wherever they are, hear questions and recitations. In those subjects where total teaching is practical there can be a saving of manpower.

TEACHER TRAINING

This year, the Cortland system is being used 1 hour, 3 days a week, for a training program designed to improve instruction. Teachers in eight schools in three districts are enrolled. Television is the most convenient and economical method for conducting this type of interdistrict training program. The benefits received by faculty members through this training experience can be significant indeed.

System Expansion

This system of communications has been designed with the idea of expansion in mind. While the coaxial cable now accommodates two channels, a total of six channels can be made available. Cable could be extended to several smaller towns and villages to serve more classes of elementary and secondary school pupils. Expansion within present schools is also possible.

Broadcast reception in the southwest area of New York State is poor, so poor that many of the communities use community antenna systems. It is possible to feed all of these systems from the Cortland project. This distribution would cover ten cities and several smaller communities. In fact, this project has been designed to serve education in so many ways, expansion is almost limitless.

Problems for the Future

There has been, during the past 2 years, a great deal of experimentation at all levels of education involving many forms of educational television. Generally, there have been as many philosophies and objections as there have been centers of experimentation. Out of it all has come two observations: (1) There is no damage to learning when the medium of television and excellence of performance are combined to communicate a lesson and (2) when conditions are right pupils have accepted the use of the medium. As a matter of fact, there is evidence indicating pupils prefer television lessons when faced with a choice between having an outstanding teacher or not. Therefore, the questions of learning and acceptance by pupils have been resolved fairly well.

Assuming that television is an effective means of communication in education, then there are three other factors which need attention immediately:

1. How can the typical school schedule be altered so that television facilities can be used in making a maximum contribution for the learner?
2. How can the school curriculum be altered so that those facts and concepts most adaptable can be used on television?
3. How can professional educators, the classroom teachers, be encouraged to use the medium to benefit learners?

These are challenges which cannot be dealt with lightly. Administrators are interested in knowing the conditions which warrant a cable installation. One measure may be the number of pupils required per mile of cable so that the cost of pupil is reasonable.

Parents are requiring top quality education for their children. They are aware of the problems involved in providing quality and excellence in education with the pending teacher shortage, inexperienced teachers, and the mounting costs. They are looking to the use of television for answers to some of the growing problems. Therefore, it is important for engineers, technicians, and educators to join in a thoughtful, professional search to discover the most appropriate and effective use of television for the improvement of instruction in education.

The Characteristic Impedance and Phase Velocity of a Shielded Helical Transmission Line

HERBERT S. KIRSCHBAUM
MEMBER AIEE

Synopsis: This paper presents the results of a theoretical and experimental investigation of the properties of a shielded helix when used as a transmission line. Since such a structure is dispersive and because of the presence of both TM and TE modes it cannot be said to have a characteristic impedance in the true sense. However, such an impedance is defined for low frequencies in terms of a distributed capacitance and inductance. These parameters, the capacitance and the inductance are determined in the case of infinite wave length for round wire helices. The equations are developed for a uniform dielectric inside the shield and for two dielectrics, one inside the helix and the other between the helix and the shield. The analytic results are then shown to agree very well with the experimental results obtained by the author.

HELICAL STRUCTURES have long been used in various ways as electromagnetic devices. In particular, they occur in the windings of core type transformers, video delay lines, traveling wave tubes, and as antenna structures. As a result of the interest in this structure, numerous reports have appeared describing the efforts made to analyze and measure the properties of a helix used as an electromagnetic device.

A helical structure can take many forms. Some of these are: a helix of infinite extent existing in an unbounded uniform medium; a helix of infinite extent in which the medium inside the helix radius is different from that outside; a shielded helix with either a uniform medium inside the shield or as in the previous situation, two media present. The greatest effort has been confined, in the past, to the first one of these forms, namely, the infinite helix in an unbounded uniform medium. The problem, in this case, is one of finding those solutions of the homogeneous Maxwell equations which satisfy the boundary conditions at the helix and at infinity. From these solutions, the various modes of operation of the helix can be evaluated.

In the case of a shielded helical transmission line, the problem is one of finding those solutions of the homogeneous Maxwell equations which satisfy the boundary conditions at the helix and at the shield. When used as a transmission line, the greatest interest is centered upon the characteristic impedance and phase constant of the helical line. Strictly speaking, the impedance concept is not a correct one when applied to a helical transmission line, since the waves present are a mixture of both transverse magnetic and transverse electric waves. Any impedances so developed apply only to relatively low frequencies, and they completely break down at a frequency where the circumference of the helix is equal to about one to two wave lengths. Beyond this frequency, the helix operates in many different modes, each with its own phase velocity.

This investigation treats the shielded helix as a distributed circuit transmission line. The inductance and capacitance parameters are derived for a quasi-round wire helix for infinite wave length. While these parameters have real meaning for direct current only, they should prove useful up to frequencies at which the wave length becomes equal to 1 to 2 circumferences. These inductance and capacitance parameters are used to derive expressions for the characteristic impedance and phase velocity of a shielded helix.

The Distributed Capacitance and Inductance

Because of the complexity involved in the development of the transmission line

This paper is an abstract of a dissertation by this author which was presented to the Carnegie Institute of Technology, Pittsburgh, Pa., in partial fulfillment of the requirements for a degree of Doctor of Philosophy.

parameters, these derivations have been omitted. For those interested in the details of the derivations, reference 1 should be consulted. In this section, a brief description will be given of the methods used to develop the expressions for the transmission line parameters along with the final results. This will be followed by an application of these results to the problem of determining the characteristic impedance of the helical transmission line and also its phase velocity. They are then compared with experimental results obtained by this author.

Two of the parameters with which the behavior of a transmission line can be described are the distributed capacitance in, say, farads per meter of line length and the distributed inductance in, say, henrys per meter of line length. Since the transmission line of this report consists of a helix formed of round wire surrounded by a perfectly conducting sheath, there are two possible definitions of line length. The first of these might be measured in the axial direction. The second might be measured in the helix direction. Since the propagation of energy along such a line is actually in the axial direction, the former definition of line length is preferred. The capacitance and inductance parameters are developed per meter in the helix direction and then written in terms of line length in the axial direction.

The transmission line with which this paper is concerned consists of a helix of round wire formed by winding it upon a supporting tube or rod of dielectric material as shown in Figs. 1 and 2. The return conductor consists of a conducting sheath which is outside the helix and coaxial with the axis of the helix. The space between the helix and the sheath may be free space or may be filled with some dielectric such as oil, polystyrene, etc. For the purposes of determining the capacitance per unit length, the transmission line is assumed to be infinitely long.

In reference 1 a rather complete formulation of the problem of the capacitance is presented. It will suffice here to present some of the more salient features of the derivation. The method of approach used is to disregard the actual boundary at the surface of the wire and to replace it with a boundary that closely approximates the surface of the wire. The necessity for doing this lies in the intractability of Laplace's equation when written in a co-ordinate system which will describe the surface of the helical wire. Furthermore, any such co-ordinate system would not contain the sheath as one of its co-ordinate surfaces.

A potential function is derived which satisfies Laplace's equation in a circular cylindrical co-ordinate system and which also satisfies the boundary conditions, that the potential at the sheath is zero and that the discontinuity in the radial component of the displacement vector, at the helix radius, be equal to the surface charge density on a very narrow tape helix. When the width of this tape is allowed to approach zero, the tape helix degenerates into a line helix of infinitesimal cross section having a uniform charge of Q_l coulombs per meter in the helix direction. The potential function so derived approaches infinity as one approaches the line helix.

Considering only a region in the immediate vicinity of the line, the equipotential surfaces are very close to right circular cylinders formed into the shape of a helix. This is the case since, as the line charge is approached very closely, the helical line appears to approach an infinitely long straight line of charge and it is known that the equipotential surfaces around such a line of charge are right circular cylinders. One of these equipotential surfaces is chosen as the surface of the wire. Although such a surface does not coincide with the actual wire surface, the agreement between it and the wire for very small wires is sufficiently close for practical applications. The potential of this equipotential surface when divided by the charge in coulombs per meter yields the reciprocal of the distributed capacitance. The procedures outlined above are carried out in detail in reference 1, the results being

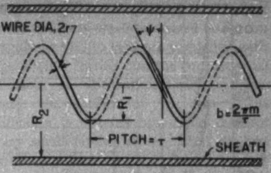

Fig. 1. Shielded helix showing dimensions

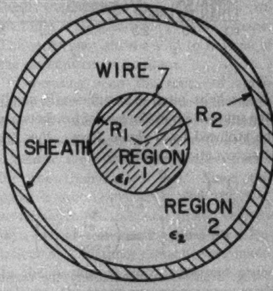

Fig. 2. Cross section of shielded helix showing regions 1 and 2

Any consistent system of length units may be used since all lengths enter as dimensionless ratios. The permitivities ϵ_1 and ϵ_2 are those of regions 1 and 2 defined in Fig. 2. Normally ϵ_1 is greater than ϵ_2, but in the case where they are equal, equation 2 reduces to

$$\frac{1}{C}=\frac{R_1}{\epsilon_2 r\cos\psi}\left\{\operatorname{Log}_e\frac{R_2}{R_1}+2\sum_{m=1}^{\infty}\frac{\left[1-\frac{I_m(bR_1)K_m(bR_2)}{I_m(bR_2)K_m(bR_1)}\right]I_m(bR_1)K_m(bR_1)\cos\left(\frac{br}{\cos\psi}\right)}{\frac{\epsilon_1}{\epsilon_2}+\left(\frac{\epsilon_1}{\epsilon_2}-1\right)\left[1-\frac{I_m'(bR_1)K_m(bR_2)}{I_m(bR_2)K_m'(bR_1)}\right](bR_1)I_m(bR_1)K_m'(bR_1)}\right\} \tag{1}$$

where b is equal to $(2\pi m/\tau)$. Or

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\left\{\operatorname{Log}_e\frac{R_2}{R_1}+2\sum_{m=1}^{\infty}\frac{\left[1-\frac{I_m(bR_1)K_m(bR_2)}{I_m(bR_2)K_m(bR_1)}\right]I_m(bR_1)K_m(bR_1)\cos\left(\frac{br}{\cos\psi}\right)}{\frac{\epsilon_1}{\epsilon_2}+\left(\frac{\epsilon_1}{\epsilon_2}-1\right)\left[1-\frac{I_m'(bR_1)K_m(bR_2)}{I_m(bR_2)K_m'(bR_1)}\right](bR_1)I_m(bR_1)K_m'(bR_1)}\right\} \tag{2}$$

where C is the capacitance per meter in the helix direction and C_z is the capacitance per meter in the axial direction. The I_m and K_m functions are modified Bessel functions of order m and of the first and second kinds, respectively. The I_m' and K_m' functions are derivatives of the modified Bessel functions with respect to the argument $(b\rho)$. The other dimensions are as defined in Figs. 1 and 2.

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\left\{\operatorname{Log}_e\frac{R_2}{R_1}+2\sum_{m=1}^{\infty}\left[1-\frac{I_m(bR_1)K_m(bR_2)}{I_m(bR_2)K_m(bR_1)}\right]\times I_m(bR_1)K_m(bR_1)\cos\left(\frac{br}{\cos\psi}\right)\right\} \tag{3}$$

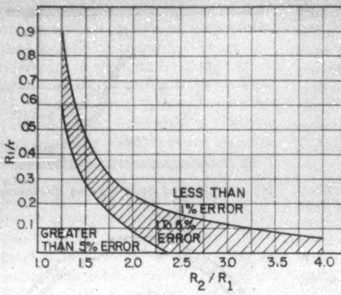

Fig. 3. Estimate of errors expected using simplified expressions for capacitance and inductance

If the helix pitch τ is sufficiently small, the summation in the pair of brackets can be replaced by a closed form. For this case, equation 2 becomes,

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\left\{\log_e \frac{R_2}{R_1}-\frac{2\epsilon_2}{\epsilon_1+\epsilon_2}\times \sin\psi\cdot\log_e\left[2\sin\left(\frac{\pi r}{\tau\cos\psi}\right)\right]\right\} \tag{4}$$

Fig. 3 shows approximately the range of R_1/τ for which equation 4 can be used and still be within a specified percentage of equation 2. This figure actually shows the error to be expected in the characteristic impedance resulting from the use of equation 4 and a similar expression for inductance. Since the capacitance, inductance, and impedance expressions are very similar, the curves in Fig. 3 give a good indication of the range of helix dimensions for which equation 4 is applicable.

If on the other hand the helix pitch τ approaches infinity, the inner conductor becomes a straight wire parallel to the axis and displaced from it by a distance R_1. Within the radius R_1 the permittivity is ϵ_1, and between R_1 and R_2 it is ϵ_2. For very long pitches the capacitance becomes approximately

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\left\{\log_e \frac{R_2}{R_1}+\frac{2\epsilon_2}{\epsilon_1+\epsilon_2}\times \sum_{m=1}^{\infty}\frac{\left[1-\left(\frac{R_1}{R_2}\right)^{2m}\right]\cos\left(\frac{mr}{R_1}\right)}{m\left[1-\left(\frac{\epsilon_1-\epsilon_2}{\epsilon_1+\epsilon_2}\right)\left(\frac{R_1}{R_2}\right)^{2m}\right]}\right\} \tag{5}$$

For the case in which $\epsilon_1=\epsilon_2$ this becomes

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\left\{\log_e \frac{R_2}{R_1}+ \sum_{m=1}^{\infty}\left[1-\left(\frac{R_1}{R_2}\right)^{2m}\right]\frac{\cos\left(\frac{mr}{R_1}\right)}{m}\right\} \tag{6}$$

This can be written in the following closed form:

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\left\{\log_e \frac{R_2}{R_1}+ \frac{1}{2}\log_e\left[\frac{1-2\left(\frac{R_1}{R_2}\right)^2\cos\frac{r}{R_1}+\left(\frac{R_1}{R_2}\right)^4}{2\left(1-\cos\frac{r}{R_1}\right)}\right]\right\} \tag{7}$$

For very small r/R_1 as compared with unity, this becomes

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\left\{\log_e \frac{R_2}{r}\left(1-\frac{R_1^2}{R_2^2}\right)\right\} \tag{8}$$

The exact expression for the capacitance between two parallel cylinders which are not coaxial is given in reference 2, page 76. The capacitance there derived, in the notation of this author, is

$$\frac{1}{C_z}=\frac{1}{2\pi\epsilon_2}\cosh^{-1}\left\{\frac{R_2}{2r}\left(1-\frac{R_1^2}{R_2^2}\right)+\frac{r}{2R_2}\right\} \tag{9}$$

This expression will approach equation 8 as (r/R_2) becomes very small. Depending upon the range of applicability, any one of the capacitances presented above may be used with the inductance per meter, to arrive at a characteristic impedance and phase velocity for the transmission line. Since this report is concerned mainly with characteristic impedance and phase velocity, no calculations of capacitance as such were made. In the sections on impedance and phase velocity, the above expressions were used, where applicable, to determine a family of impedance and phase velocity curves.

In reference 1 a rather complete formulation of the problem of the distributed inductance is given. As in the case of the capacitance, the actual wire is not used to form the boundary of the helix. Instead, a different surface which closely approximates the actual wire is used in place of the wire. It is shown that the inductance of the helix can be arrived at be a complete knowledge of the vector potential of electric current in the region surrounding the helix. The inductance so calculated neglects any internal flux in the wire, this assumption being based upon the fact that the frequencies at which this structure is used, the current in the wire will be confined to the surface of the wire. The vector potential is arrived at by solving in cylindrical coordinates what might be called the vector equivalent of Laplace's equation, along with the requirement that the divergence of the vector potential be zero. These two equations, which must be satisfied in the magnetostatic case, are

$$\nabla\times\nabla\times A=0 \tag{10}$$

$$\nabla\cdot A=0 \tag{11}$$

where A is the vector potential of electric current in the current free region surrounding the helix. The vector potential and the magnetic field which can be derived from it must satisfy certain boundary conditions. The most important of these is, that the magnetic field outside the sheath be zero and that the discontinuity in the tangential component of the H vector at the helix radius, R_1, be numerically equal to the current density in a very narrow tape helix at R_1. When the width of the tape is allowed to approach zero, the tape degenerates into a line helix of infinitesimal cross section carrying a current of I amperes. The vector potential so derived approaches infinity as one approaches the helical line. If one approaches the line sufficiently close, the distance between the line and the observer becomes small compared with the radius of curvature of the line. In this case the helical line may be approximated by an infinite straight line carrying current. The surfaces of equi-vector-potential which surround such a straight line of current are known to be right circular cylinders. A round wire carrying current in which the current density in the wire is a function of the radius only, also has equi-vector-potential surfaces which are right circular cylinders. In fact the wire surface itself is an equi-vector-potential surface. Therefore, as an approximation, one of the equi-vector-potential surfaces which surrounds the line helix is used as the surface of the wire. This approximation approaches perfection as the wire radius approaches zero. As is shown in reference 1, the magnitude of the vector potential in the helix direction at the wire surface when multiplied by (μ_0/I) yields the inductance per meter in the helix direction.

Vol.
Pt. 1
1959

The procedure outlined in the preceding paragraph is carried out in detail,[1] and the results of this work are given in several forms:

$$L=\frac{\mu_0 R_1 \cos\psi}{\tau}\left\{\frac{1}{2}\left(1-\frac{R_1^2}{R_2^2}\right)+\tan^2\psi\cdot\log_e\frac{R_2}{R_1}-2\sum_{m=1}^{\infty}\left[1-\frac{I_m'(bR_1)K_m'(bR_2)}{I_m'(bR_2)K_m'(bR_1)}\right]\times I_m'(bR_1)K_m'(bR_1)\cos\left(\frac{br}{\cos\psi}\right)\right\} \quad (12)$$

where L is the inductance in henrys per meter in the helix direction. The other dimensions are defined in Figs. 1 and 2. Any consistent system of length may be used since all lengths enter as dimensionless ratios. If L_z is used to denote the inductance per meter in the axial direction, equation 12 becomes

$$L_z=2\pi\mu_0\left(\frac{R_1}{\tau}\right)^2\left\{\frac{1}{2}\left(1-\frac{R_1^2}{R_2^2}\right)+\tan^2\psi\cdot\log_e\frac{R_2}{R_1}-2\sum_{m=1}^{\infty}\left[1-\frac{I_m'(bR_1)K_m'(bR_2)}{I_m'(bR_2)K_m'(bR_1)}\right]\times I_m'(bR_1)K_m'(bR_1)\cos\left(\frac{br}{\cos\psi}\right)\right\} \quad (13)$$

If the helix pitch is sufficiently small, the summation in the brackets can be replaced by a closed form. For this case equation 13 becomes

$$L_z=2\pi\mu_0\left(\frac{R_1}{\tau}\right)^2\left\{\frac{1}{2}\left(1-\frac{R_1^2}{R_2^2}\right)+\tan^2\psi\times\left[\log_e\frac{R_2}{R_1}-\frac{1}{\sin\psi}\log_e\left(2\sin\left(\frac{\pi r}{\tau\cos\psi}\right)\right)\right]\right\} \quad (14)$$

Fig. 3 shows the range of R_1/τ for which equation 14 can be used with reasonable accuracy. Although this figure is strictly applicable to the characteristic impedance, it is sufficiently accurate to indicate for what range of (R_1/τ) good results can be expected from equation 14.

For a very close wound helix of small wire, the second term within the bracket becomes negligible and the above expression reduces to,

$$L_z=\pi\mu_0\left(\frac{R_1}{\tau}\right)^2\left(1-\frac{R_1^2}{R_2^2}\right) \quad (15)$$

This checks previously derived results[2] for very close wound helices in shielding cans.

On the other hand, if the pitch of the helix becomes very large it approaches a straight wire parallel to the axis of the sheath and displaced from the axis by a distance of R_1. Hence for a very long pitch the inductance becomes approximately

$$L_z=\frac{\mu_0}{2\pi}\left\{\log_e\frac{R_2}{R_1}+\sum_{m=1}^{\infty}\left[1-\left(\frac{R_1}{R_2}\right)^{2m}\right]\frac{\cos\left(\frac{mr}{R_1}\right)}{m}\right\} \quad (16)$$

This can be expressed in the following closed form:

$$L_z=\frac{\mu_0}{2\pi}\left\{\log_e\frac{R_2}{R_1}+\frac{1}{2}\times\log_e\left[\frac{1-2\left(\frac{R_1}{R_2}\right)^2\cos\frac{r}{R_1}+\left(\frac{R_1}{R_2}\right)^4}{2\left(1-\cos\frac{r}{R_1}\right)}\right]\right\} \quad (17)$$

For very small r/R_1 as compared with unity, this becomes

$$L_z=\frac{\mu_0}{2\pi}\left\{\log_e\frac{R_2}{r}\left(1-\frac{R_1^2}{R_2^2}\right)\right\} \quad (18)$$

When this expression is used along with equation 8 to compute the characteristic impedance of this degenerate helix ($\tau=\infty$), there results an expression which is in agreement with the accepted[4] impedance for this structure. This validates equation 14 for the case of infinitely long pitch.

The expressions in this section for the inductance and in the previous section for the capacitance are based upon very small wire radii. However, if the pitch of the helix becomes of the same order of magnitude as the wire diameter, the wire radius, while still very small compared to R_1, can hardly be said to be small compared with the pitch. In this case the equipotential surfaces do not satisfactorily approximate the surface of the wire. This difficulty is vitiated by noting that for very small pitches all terms but the first within the braces of equation 13 become negligibly small. Since the first term is independent of the wire diameter it may be concluded that for very close wound small wire helices the distributed inductance is independent of the wire shape. The same may also be said to be true of the distributed capacitance.

Depending upon the range of applicability, any one of the above inductances may be used with the appropriately chosen capacitance to arrive at a characteristic impedance and phase velocity for the transmission line. Since this paper is concerned mainly with the characteristic impedance and phase velocity of a helical transmission line, no calculations of inductance as such were made. In the section on impedance and phase velocity, the above expressions were used, where applicable, to determine a family of impedance and phase velocity curves.

Characteristic Impedance and Phase Velocity

When a distributed circuit transmission line which has an inductance L_z per unit length and a capacitance C_z per unit length is studied, it is found that it can sustain traveling waves of current and voltage. In the absence of losses, it is found that these waves travel unattenuated with a velocity v_z which is independent of frequency. At any point the ratio of voltage to current is also a constant Z_0 which is independent of frequency. These two constants, the phase velocity and characteristic impedance, are related to the inductance and ca-

pacitance parameters as follows:

$$Z_0=\sqrt{\frac{L_2}{C_2}} \tag{19}$$

$$v_z=\frac{1}{\sqrt{L_2C_2}} \tag{20}$$

The inductance and capacitance parameters were derived upon the assumption of infinite wave length. Consequently these constants have meaning only so long as the wave length is quite long compared with the pitch of the helix. The basis for this assertion is the fact that the mutual effect of the turns of the helix upon any one given turn becomes smaller as the distance between them increases. Therefore, it is the turns closest a given one that have the greatest effect upon its inductance and capacitance. If the wave length is long, the turns in the vicinity of any one given turn are essentially at the same potential and carry essentially the same current and the above parameters have real meaning.

By using equation 2 and 13 in equation 19 one obtains for the characteristic impedance,

$$Z_0=\frac{R_1}{\tau}\sqrt{\frac{\mu_0}{\epsilon_2}}\cdot\sqrt{F_1F_2} \tag{21}$$

where

$$F_1=\left\{\log_e\frac{R_2}{R_1}+2\sum_{m=1}^{\infty}\frac{\left[1-\frac{I_m(bR_1)K_m(bR_2)}{I_m(bR_2)K_m(bR_1)}\right]I_m(bR_1)K_m(bR_1)\cos\left(\frac{br}{\cos\psi}\right)}{\frac{\epsilon_1}{\epsilon_2}+\left(\frac{\epsilon_1}{\epsilon_2}-1\right)\left[1-\frac{I_m'(bR_1)K_m(bR_2)}{I_m(bR_2)K_m'(bR_1)}\right](bR_1)I_m(bR_1)K_m'(bR_1)}\right\} \tag{22}$$

$$F_2=\left\{\frac{1}{2}\left(1-\frac{R_1^2}{R_2^2}\right)+\tan^2\psi\cdot\mathrm{Log}_e\frac{R_2}{R_1}-2\sum_{m-1}^{\infty}\left[1-\frac{I_m'(bR_1)K_m'(bR_2)}{I_m'(bR_2)K_m'(bR_1)}\right]\times I_m'(bR_1)K_m'(bR_1)\cos\left(\frac{br}{\cos\psi}\right)\right\} \tag{23}$$

The expression given by equation 21 is of course very general and for certain ratios of (R_1/τ) simpler results can be used. For (R_1/τ) sufficiently large, the factors F_1 and F_2 become

$$F_1=\left\{\log_e\frac{R_2}{R_1}-\frac{2\epsilon_2}{\epsilon_1+\epsilon_2}\sin\psi\cdot\log_e\left[2\sin\left(\frac{\pi r}{\tau\cos\psi}\right)\right]\right\} \tag{24}$$

$$F_2=\left\{\frac{1}{2}\left(1-\frac{R_1^2}{R_2^2}\right)+\tan^2\psi\cdot\left[\mathrm{Log}_e\frac{R_2}{R_1}-\frac{1}{\sin\psi}\cdot\log_e\left(2\sin\left(\frac{\pi r}{\tau\cos\psi}\right)\right)\right]\right\} \tag{25}$$

On the other hand for R_1/τ sufficiently small, using equations 5 and 18,

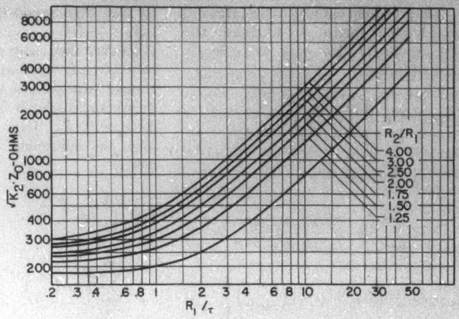

Fig. 5. Characteristic impedance versus R_1, τ, and R_2

$$Z_0=\frac{1}{2\pi}\sqrt{\frac{\mu_0}{\epsilon_2}}\cdot\sqrt{G_1G_2} \tag{26}$$

where

$$G_1=\left\{\log_e\frac{R_2}{R_1}+\frac{2\epsilon_2}{\epsilon_1+\epsilon_2}\times\sum_{m=1}^{\infty}\frac{\left[1-\left(\frac{R_1}{R_2}\right)^{2m}\right]\cos\left(\frac{mr}{R_1}\right)}{m\left[1-\left(\frac{\epsilon_1-\epsilon_2}{\epsilon_1+\epsilon_2}\right)\left(\frac{R_1}{R_2}\right)^{2m}\right]}\right\} \tag{27}$$

$$G_2=\left\{\log_e\frac{R_2}{r}\left(1-\frac{R_1^2}{R_2^2}\right)\right\} \tag{28}$$

By using equations 2 and 13 in equation 20, one obtains for the phase velocity in the axial direction,

$$v_z=\frac{\tan\psi}{\sqrt{\mu_0\epsilon_2}}\sqrt{\frac{F_1}{F_2}} \tag{29}$$

where F_1 and F_2 are given by either equations 22 and 23 or by equations 24 and 25. The latter pair are for close wound helices. On the other hand if R_1/τ is sufficiently small, using equations 5 and 18,

$$v_z=\frac{1}{\sqrt{\mu_0\epsilon_2}}\sqrt{\frac{G_1}{G_2}} \tag{30}$$

where G_1 and G_2 are given by equations 27 and 28. In the event $\epsilon_1=\epsilon_2$ equation 30 reduces to the velocity of light in a medium characterized by the permeability μ_0 and the permittivity ϵ_2.

Some Examples

As an example consider a helical transmission line for which the dimensions are tabulated as follows:

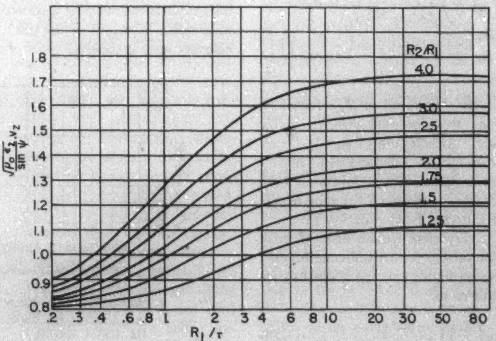

Fig. 6. Phase velocity versus R_1, τ, and R_2

Vol.
Pt. 1
195

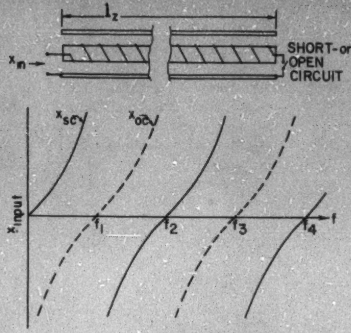

Fig. 7 (above). Test setup with typical results

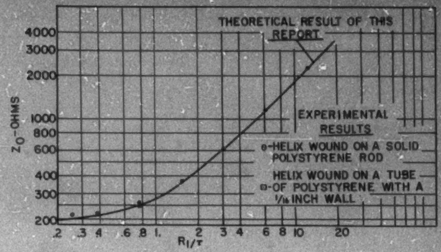

Fig. 8 (top right). Comparison of theoretical and experimental characteristic impedances

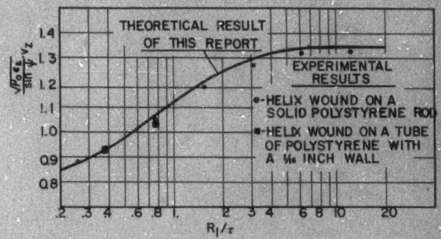

Fig. 9 (right). Comparison of theoretical and experimental phase velocities

$R_1=0.385$ inch
$R_2=0.750$ inch
$r=0.010$ inch
$\tau=$variable
$\epsilon_1=2.6\ \epsilon_0$
$\epsilon_2=1.0\ \epsilon_0$
$\epsilon_0=8.854\times10^{-12}fd/m$

These dimensions were chosen since they correspond to those for a series of helices tested by the author.

Fig. 4 shows the impedance as calculated from the close wound helix approximation which is embodied in equations 21, 24, and 25. This approximation was applied over the range of R_1/τ from 0.02 to 10.0. Of course, at the lower end of the range the helix can hardly be said to be close wound. Also in Fig. 4 is plotted the exact impedance as embodied in equations 21, 22, and 23. It is interesting to note that at $R_1/\tau=0.02$ they differ by only 8%.

Extensive families of curves have been calculated showing the characteristic impedance and phase velocity of wire helices. Typical examples of such families are shown in Figs. 5 and 6. For a more complete set of these curves, see reference 1.

Experimental Results

Other authors have conducted experimental work on the impedance and phase velocity of shielded helices. However, this author has conducted similar experimental work because the reports of the previous investigators left some doubts concerning the manner of testing or the actual dimensions, etc., of their helices. As will be shown, the work of this investigator agrees closely with the analytic results presented in the previous sections.

The method of testing used by the present author does not measure the characteristic impedance and phase velocity directly. These are determined from a measurement of the open-circuit and short-circuit driving point impedances of the transmission line. Fig. 7 shows the results which would be obtained from a typical set of measurements on a given lossless helical transmission line of axial length l_z. From transmission line theory applied to a lossless transmission line, the open- and short-circuit impedances are pure reactance. They are

$$X_{sc}=j\sqrt{\frac{L_z}{C_z}}\tan\left(2\pi f l_z\sqrt{L_zC_z}\right) \qquad (31)$$

$$X_{oc}=-j\sqrt{\frac{L_z}{C_z}}\cot\left(2\pi f_z\sqrt{L_zC_z}\right) \qquad (32)$$

where X_{sc} and X_{oc} are the short-circuit and open-circuit driving point impedances respectively. The parameters L_z and C_z are the distributed inductance and capacitance per unit of length in the axial direction. From equations 31 and 32,

$$Z_0=\sqrt{\frac{L_z}{C_z}}=\sqrt{|X_{sc}|\cdot|X_{oc}|} \qquad (33)$$

$$v_z=\frac{1}{\sqrt{L_zC_z}}=4f_1l_z \qquad (34)$$

where f_1 is the frequency of the first "pole" in the short-circuit driving point impedance. This frequency is also that at which the transmission line is one quarter of a wavelength long. Thus by measuring the open- and short-circuit driving point impedances for frequencies up to that at which the line becomes one quarter of a wavelength long, the characteristic impedance and phase velocity can be determined from equations 33 and 34.

The analytic results of the previous section were arrived at by assuming infinite wave length. Because of this, the experimental results are confined to frequencies for which the transmission line length is equal to or less than one quarter wavelength.

All of the helices tested had the same R_1, R_2 and wire radius r. These were respectively 0.385 inch, 0.750 inch, and 0.010 inch. The winding pitch was varied from 1/32 inch up to $1^1/_2$ inches. The outer conductor or sheath consisted of a 1.5-inch copper tube 72 inches long with a wall thickness of 1/8 inch. The first two helices, nos. 1 and 2, were wound on a polystyrene tube having a 3/4-inch outside diameter and a 1/16-inch wall. These helices were 72 inches long and were supported concentrically in the copper tube by three polystyrene supports placed at both ends and the middle. These supports were 1/8 inch thick and their effect was assumed to be negligible. The helix was made very long in order to

Table I. Comparison of Test and Analytical Results as Obtained by the Author

* Calculated for a solid core.

eliminate from consideration any end effects, the analysis being based upon an infinitely long helix. Helices 3 to 8 were the same as 1 and 2 in all respects except that they were wound on 3/4-inch solid polystyrene rod and were 71 inches long. Table I gives the $R_1\tau$ of the various helices along with the calculated and measured properties.

These results are plotted in Figs. 8 and 9. At the lower end of the range of R_1/τ, the measured impedances lie somewhat above the calculated impedances. This is probably because of the fact that the theoretical result is based upon the assumption that the dielectric material of the supporting rod extends out to a radius R_1. In actuality, it falls short of this by an amount equal to the wire radius. In Fig. 9 the phase velocity compares very favorably with the theoretical curve, the maximum deviation being 3%. One thing apparent from the test results is that it makes very little difference whether the helix is wound on a solid rod or upon a tube.

Conclusion

This paper has presented the results of a theoretical and experimental study of the properties of a shielded helical transmission line. It has been shown that the parameters of a shielded wire helix can be satisfactorily computed by replacing the actual equipotential surface of the wire by an equivalent surface. These results should prove useful in a number of applications where such a structure appears.

Precision Integrator for D-C Potentials

JOHN R. PATTEE
MEMBER AIEE

INTEGRATORS of small direct currents and potentials have been put to good use in a wide variety of applications, such as in measuring photographic exposure by time-integrating the output of a photovoltaic cell, in registering watt-hours derived from the d-c millivolt (mv) output of thermal watt converters and electronic watt converters, and in tallying the amount of gold consumed in gold-plating operations by integrating the potential drop in the plating current shunt.

General Description

A d-c integrator will be described which utilizes a d-c amplifier and a motor-driven tachometer d-c generator providing feedback potential as principal operating elements. The input circuit is free of make-and-break contacts and the amplifier gain is very high, so that a calibration accuracy of 0.1% is regularly achieved and potentials as low as 5 μv (microvolts) are resolved. Potentials may be of either polarity or may fluctuate back and forth through zero. Values of the integral are almost continuously registered by a mechanical counter directly driven by the motor generator, and the values increase or decrease according to the polarity of the input.

In this class of integrator, the basic process consists of amplifying the difference between the input potential to be time integrated and the output potential of a small d-c generator having a permanent-magnet field. The amplified difference controls the operation of a servomotor driving the generator. A fixed quantity of mv-seconds is generated at every revolution, being proportional only to the amount of flux cut by the revolving armature windings and the number of their turns, but independent of speed. When the generated mv-seconds are fed back in series opposition to the input mv-seconds, the two will sooner or later come into balance, because any remaining difference appears as voltage to drive the motor generator. Because servomechanisms have inertia and a dead zone, it is necessary to provide a surge capacitor and series resistor across the output of the d-c amplifier. The resistor is a mutual resistance between output and input circuits so that electricity is fed into the capacitor when the input potential is higher than the generator feedback, and is drawn out when the potential is lower. This action will be described in detail later in the paper.

Amplifier

It is generally known that the amplification of d-c potentials of a few mv with long-time stability presents serious problems because of thermal drift and noise. R. W. Gilbert has described a highly-stable d-c amplifier utilizing an induction galvanometer to convert small input currents to alternating current of high frequency.[1] This causes frequency modulation of an oscillator, the output of which is converted to bidirectional direct current in a discriminator. The input end consists simply of a galvanometer coil in series with the primary of a small 200-

Y., February 1–6, 1959. Manuscript submitted November 5, 1958; made available for printing December 17, 1958.

JOHN R. PATTEE is with Central Research Laboratory, Weston Electrical Instrument Corporation, Newark, N. J.

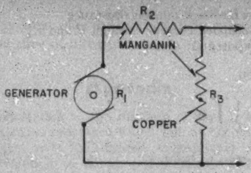

Fig. 1 (left). Temperature - compensated generator

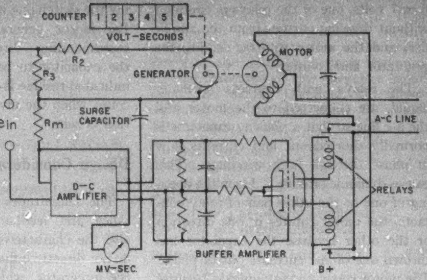

Fig. 2 (right). Schematic diagram

kc transformer. Over-all gain is very high, so that potentials as low as 5 μv are resolved.

This amplifier, named Inductronic,* is primarily responsible for the high accuracy and resolution achieved by the integrators described here. Accuracy is not materially affected by amplifier gain (as long as it is very high), nor by the magnitude of the mutual resistor or surge capacitor.

Generator

Accuracy also depends on the performance of the generator. This is a high-quality tachometer generator of a type which has been manufactured for many years so that its reliability in measurement service has been well established. The field magnet is of cobalt steel and brushes and commutator are of silver. It is operated at a speed far below that of normal service. A steel enclosure shields it from stray fields. Temperature compensation is provided to offset the negative temperature coefficient of the magnet, which is approximately −300 parts per million. Two methods have been applied. One consists of placing a magnetic shunt next to the magnet, the shunt being made of nickel-iron alloy with a negative coefficient of permeability. A similar method is used to compensate temperature influence on watt-hour-meter magnets. A difficulty in applying this method is that the shape and size of the shunt cannot be calculated, but must be determined by cut-and-try.

The second method consists of connecting a voltage divider across the generator output. As shown in the diagram of Fig. 1, the shunt branch has a section of copper wire. The positive coefficient of this section raises the proportion of the generated voltage appearing across that branch with rising temperature, while the field strength and generated voltage fall. The generator must be driven at sufficient speed to provide the voltage drop across the series branch as well as the required output voltage.

A mathematical analysis of generator temperature compensation is presented in the Appendix. The calculated values of resistance are only approximate because values of temperature coefficients which have been assigned to the components are not exact. The temperature coefficient of manganin is usually not quite zero as assigned, and the coefficient of the magnet may not be known to a high degree of accuracy. Nonetheless, a divider made according to the formula does yield a very low temperature coefficient of output. A more exact formula is not considered worthwhile, partly because there are other small temperature influences of unknown magnitude, such as dimensional changes. If high-precision compensation is required, a compensated generator is made according to the formula and tested over the required temperature range. If temperature influence is too high, it is a simple matter to make a small adjustment in the copper-to-manganin ratio of the shunt to correct it.

It is, of course, necessary that the temperature of the magnet, the armature winding, and the copper section of the shunt remain at the same temperature. Practically this means that they must be placed close together, shielded from concentrated external temperature variations, and substantially free of self-heating. All these requirements are met in the present design. The whole generator is enclosed in a steel shield. It has a cast-aluminum case completely enclosing magnet, armature, and resistors. All three resistors are wound on a small spool which is bolted to a part of the aluminum case close to the magnet and armature. Since the output is only 3 ma (milliamperes) at 270 mv, or 800 μw (microwatts), and the speed about 45 rpm, self-heating is negligible.

Detailed Description

The basic components so far discussed can be combined in several ways to form an integrator. The integrator which is the particular subject of this paper was briefly described in 1955 by R. W. Gilbert and will now be discussed in detail.[2] A simplified circuit diagram is given in Fig. 2. The block marked "d-c amplifier" represents the amplifier with induction galvanometer converter described earlier. The input circuit of the integrator consists of the amplifier input in series with a feedback resistor, R_m, and the generator, R_3. Current is fed back through the surge capacitor to the feedback resistor. The effect of this will be described in detail later. The potential across the capacitor is allowed to rise to several volts, and it (plus the small potential drop across the feedback mutual resistor) is applied to a voltmeter and to the grids of a dual triode which is a buffer between the amplifier and a pair of relays. The relays control the operation of a servomotor of low inertia which drives the generator through a 30/1 reduction gear. The motor, generator, and integral counter are connected by a chain drive. This lends flexibility to the design, so that various revolution ratios and various types of counters can be adapted without major mechanical changes. Operation of this assembly is explained in the following.

The potential to be integrated, applied to the input, produces a current output which flows through the surge capacitor and feedback resistor, rising instantly to such a value that the drop across the resistor very nearly balances the applied potential. (If the gain of the amplifier were infinite the balance would be perfect, in the absence of stray thermal electromotive forces (emfs).) An almost perfect current generator thus delivers to the surge capacitor, in proportion to the applied potential, a current which is not appreciably diminished by the rising back emf. The output potential of the amplifier goes to the grids of a dual triode having a relay in each plate circuit. When it has risen to some

---

* Registered trade-mark.

6 or 7 volts, one of the relays is operated without drawing current from the amplifier, and the motor rotates, driving the generator and counter.

The relays, with contacts normally closed, are connected to the motor and the a-c line so that a phasing capacitor is normally shorted out and currents flow in phase through both windings. This causes dynamic braking. Upon the opening of one or the other pair of relay contacts, the motor rotates in one direction or the other because the capacitor has thrown one of the currents out of phase. The motor starts up very quickly because of its low inertia.

The rotating generator delivers to its shunt a potential which, by design, is higher than the maximum rated steady-input potential and opposed to it. Then the net potential input at the amplifier is reversed, the output current reverses, and the surge capacitor is gradually discharged. At 2 or 3 volts, the contacts are closed and the motor stops suddenly with dynamic braking. In other words, current surges in and out of the capacitor, building up a potential which is an analog of the input potential-time integral, then drawing it down while the integral quantity is transferred to the counter mechanically. The cycling rate depends upon the input level, and is likely to be about 3 or 4 cps (cycles per second).

The mv-seconds produced by the generator must eventually match the mv-seconds of the source (except for a small residue represented by the charge in the surge capacitor), because any difference between them causes a current to charge the capacitor to the point where the motor generator starts up. It will run until the difference between the input mv-seconds and the quantity registered by the counter is very small. Thus, the integrating action of the counter is intermittent, but it does not lag the true value by more than 15 mv-seconds and the lag is likely to be less. When the integral has run up to 15 volt-seconds, the lag will be less than 0.1%.

When integral steps smaller than 15 mv-seconds must be resolved, a voltmeter is added which measures the analog voltage of the surge capacitor plus the small potential drop across R_m. This is the instrument, labeled "mv-sec" in Fig. 2, which indicates the residual integral not transferred to the counter. At the end of a run, the indicated value may be added arithmetically to the quantity registered by the counter, or it may be transferred to it electromechanically by operating a three-position switch, not shown, having contacts in series with the relays. Pushing the switch one way or the other causes the motor generator to rotate in a corresponding direction. This causes the capacitor to be discharged, and the indicated residue is correctly added to the count when the mv-second meter indication is zero.

Design Considerations

The magnitudes of the surge capacitance and feedback mutual resistance and the characteristics of the voltmeter do not directly influence the calibration of the integrator, which is governed solely by the generator. They are chosen to suit the characteristics of the Inductronic amplifier and the motor generator.

The generator, while running, delivers about 80 mv across the shunt, R_3. The average input potential must be below this value, so a normal average input of 70 mv has been established. The transfer characteristic of the amplifier is linear up to 1.8 ma of output. R_3 is made 100 ohms, which produces a balance of the 70-mv input with 0.7 ma, leaving an ample margin for momentary overloads.

Maintenance of transfer linearity also requires that the output potential be limited to 10 volts or less. This has a bearing on the choice of characteristics of both the voltmeter and the surge capacitor. When all other conditions are fixed, the cycling rate of the system is inversely proportional to the capacitance, C. A high cycling frequency keeps the residual integral value small but causes strain and wear of the motor and the mechanism it drives. A capacitance of 18 μf (microfarads) has been found to be a good compromise. Buffer amplifier gain and relay characteristics have been arranged to operate the relays at about 7 volts and release them at about 2 volts. The particular values are not important.

Calibrating the Millivolt-Second Meter

In view of these considerations, the full-scale range of the voltmeter is made 10 volts. A 10–0–10-volt zero-center scale is provided for reversible inputs, and a 0–10-volt scale for unidirectional systems. Although the voltmeter current, being outside the feedback loop, does not affect calibration, it is designed to be only 50 μa (microamperes) full scale in order not to overburden the amplifier. Scale calibration is in mv-seconds, and the characteristic can be determined analytically as follows, letting

e_{in} = input potential
C = capacitance of surge capacitor
R_m = feedback mutual resistance
i = feedback current through C and R_m
E_c = potential across C

Then

$$E_c = \frac{1}{C}\int i\,dt \tag{1}$$

$$iR_m = e_{in} \text{ at balance} \tag{2}$$

$$\int e_{in}dt = E_c R_m C \tag{3}$$

If $E_c = 10$ volts, $R_m = 100$ ohms, and $C = 18$ μf, $\int e_{in}dt = 18$ mv-seconds, this is the full-scale value. In practice, a complete voltmeter is procured, scaled 0–18 or 18–0–18 mv-seconds as required. The effects of tolerances in specified capacitance and voltmeter calibration are adjusted out if necessary by readjusting R_m, which does not affect the calibration of the counter. Calibration is unnecessary if the integral residue is transferred to the counter as described earlier, because the voltmeter then serves merely as a null indicator.

Capacitor Leakage

Calibration is not influenced by the currents flowing through the voltmeter and the buffer amplifier input because they are outside the feedback loop. But leakage current in the surge capacitor is a possible source of error, which can be analyzed as in the following.

Calling the capacitor resistance R_c, the leakage current will equal E_c/R_c. The potential drop it causes in the feedback resistor R_m is given by:

$$\text{Error potential} = E_c\frac{R_m}{R_c} \tag{4}$$

If the average value of E_c is 5 volts, R_m is 100 ohms, and R_c is as low as 100 megohms, the error potential will be 5 μv, which is about the resolving power of the system. Evidently capacitors can readily be obtained which would reduce this error to a negligible value.

Although the rated average input level is 70 mv, pulses of short duration amounting to twice that level are tolerated, provided that the time integral of the overvoltage does not exceed 200 mv-seconds.

Conclusions

An integrator is described for time-integrating direct potentials up to 70 mv average value of either polarity. Currents can be integrated by means of shunts, and power by means of watt converters. Potential resolving power is 5 μv. Integral values are registered with an accuracy of 0.1% or 1 mv-second, whichever is greater, plus the product of 5 μv times the time of integration.

Appendix

Referring to the diagram of Fig. 1, the values of resistance which will, at the same time, give the desired volt-seconds per revolution at the output terminals and a null temperature coefficient of output may be derived as follows, assuming that all the significant temperature coefficients are known:

M = temperature coefficient of magnet
C = temperature coefficient of copper
S = temperature coefficient of mixed shunt
t = a reference temperature of normal room value
Δt = a change in temperature from t
G = generated volt-seconds per revolution at temperature t
Q = output volt-seconds per revolution

Assume that manganin has no temperature coefficient.

At reference temperature t:

$$\frac{Q}{G}=\frac{R_3}{R_1+R_2+R_3} \tag{5}$$

If the temperature rises:

$$\frac{Q}{G(1+M\Delta t)}=\frac{R_3(1+S\Delta t)}{R_1(1+C\Delta t)+R_2+R_3(1+S\Delta t)} \tag{6}$$

$$Q[R_1+R_2+R_3+(R_1C+R_3S)\Delta t]=GR_3[1+(M+S)\Delta t+MS(\Delta t)^2]$$

From equation 1

$$Q(R_1+R_2+R_3)=GR_3$$

therefore

$$Q(R_1C+R_3S)\Delta t=GR_3[(M+S)\Delta t+MS(\Delta t)^2] \tag{7}$$

$MS(\Delta t)^2$, since it is a very small term, can be neglected.

$$QR_1C+QR_3S=GR_3M+GR_3S \tag{8}$$

$$S=\frac{GR_3M-QR_1C}{(Q-G)R_3} \tag{9}$$

To produce a temperature coefficient of S in the shunt R_3, it is made partly of copper, partly of manganin. The proportions must be:

$$\text{Copper resistance}=R_3\frac{S}{C} \tag{10}$$

$$\text{Manganin resistance}=R_3-\text{copper resistance} \tag{11}$$

In the present integrator, the generator is wound with copper; resistance across the brushes is approximately 12.3 ohms. The field magnet is treated so that the generated output, G, is 360 mv-seconds per revolution. One hundred mv-seconds has been chosen as a convenient terminal output, Q. It is desirable to limit the generator current in the divider network to a few milliamperes. But it is also desirable to keep the total internal resistance of the integrator input below 200 ohms. Therefore, the shunt resistance R_3 has been made 30 ohms. Tabulating the values:

G = 360 mv-seconds
Q = 100 mv-seconds
R_1 = 12.3 ohms
R_3 = 30 ohms
M = −0.0003 per degree centigrade
C = 0.004 per degree centigrade

Putting these values into equation 5, S = 0.00105/C.

From equations 10 and 11, the copper section should be 7.9 ohms and the manganin section 22.1 ohms.

The value of R_2 can be derived from equation 1:

$$R_2=R_3G/Q-R_1-R_3$$

$$R_2=65.7 \text{ ohms} \tag{12}$$

Proposed Standard Test Codes for Magnetic Amplifiers

AIEE COMMITTEE REPORT

THE TEST CODES presented here were first presented in 1958 as a conference paper,[1] in substantially their present form. The slight revisions contained herein are the result of comments received since that presentation and as a result of a formal review of this paper by the Magnetic Amplifiers Committee.

It is intended that these proposed test codes be used as a guide for the industry in the obtaining and presentation of test data on magnetic amplifiers; naturally the number and type of tests selected will vary somewhat with the type and application of each particular amplifier.

As additional proposed test codes are formalized, they will be added to this list. The Test Codes Working Group is presently considering as subjects "Drift," and "Environmental Sensitivity," as well as test codes for bistable amplifiers.

Ratings

No work on magnetic amplifier ratings has been done since the presentation of a 1957 conference paper.[2] However, a separate working group is being formed this year to prepare standard ratings, including nominal ratings. For clarity and completeness in presenting the present proposed test codes, the following rating information has been extracted from the conference paper.[2]

> The rating of a magnetic amplifier consists of a statement of the values of the supply voltage, frequency, load resistance, output voltage or current, volt-ampere output, and control voltage or current assigned to it by the manufacturer. This rating shall be given for a specified connection of all components within the amplifier.
>
> . . . The magnetic amplifier shall be capable of operating continuously at [rated] supply voltage at rated frequency and with rated load . . ., for any values of output and control quantities within their ratings, without exceeding the established rating of any of its components.

Definitions

The magnetic-amplifier definitions contained in a proposed standard given in 1958[3] are adhered to. In addition, the following definitions are presented for clarity only; they are not a part of the proposed test codes, nor have they been formally approved by the Definition Subcommittee:

1. *Current amplification.* The current amplification of a magnetic amplifier is the ratio of the change in output current to the change in current in the control

---

Paper 59-177, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted November 5, 1958; made available for printing December 2, 1958.

The personnel of the Working Group on Test Codes Subcommittee of the Magnetic Amplifiers Committee are: H. L. Kellogg, *chairman*, H. W. Patton, F. G. Timmel (Working Group Chairman), H. B. Whitted, and T. G. Wilson.

The contributions of past, as well as present, members of the Standards Subcommittee of the AIEE Committee on Magnetic Amplifiers are gratefully acknowledged.

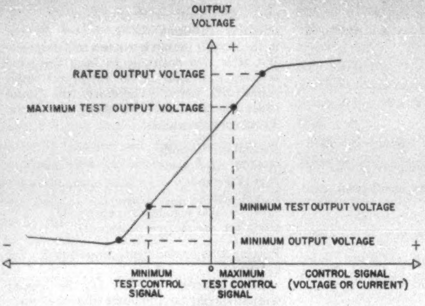

Fig. 1. Nonreversible parameters

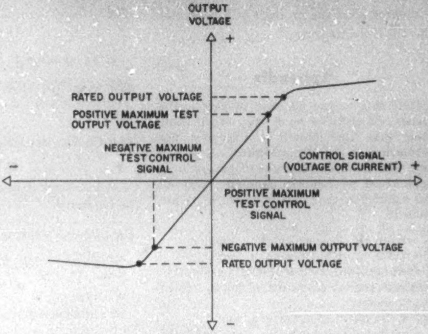

Fig. 2. Reversible parameters

winding required to produce the output current change.

2. *Figure of merit.* The figure of merit of a magnetic amplifier is the ratio of power amplification to the response time, preferably expressed in seconds.

3. *Power amplification.* The power amplification of a magnetic amplifier is the product of the voltage amplification and the current amplification.

4. *Voltage amplification.* The voltage amplification of a magnetic amplifier is the ratio of the change in output voltage to the change of voltage across the control winding circuit required to produce the output voltage change.

Proposed Standard Test Codes

I. GENERAL CONSIDERATIONS

A. *General Operating Conditions*

The magnetic amplifier should be operated at its nominal rated conditions except for its control circuit quantities and output quantities.

B. *Control Signal*

1. For the magnetic amplifiers with d-c signal, the control signal should be obtained from a voltage source which has less than 5% ripple and whose internal impedance is such that the source voltage at no time under transient or steady-state conditions decreases by more than 10% of the value which would exist if the control circuit of the magnetic amplifier were open.

a. The average magnitude of the control signal voltage should be measured at the terminals of the voltage source.*

b. Control circuit currents flowing as a result of this voltage should be measured with an average reading meter.*

2. For magnetic amplifiers with a-c signal, the control signal (carrier) should be obtained from a voltage source of power frequency and specified phase which has a total harmonic content less than 5% and whose internal impedance is such that the source voltage at no time under transient or steady-state conditions decreases by more than 10% of the value which would exist if the control circuit of the magnetic amplifier were open.

a. The magnitude of the average values (averaged over one-half cycle) of the a-c signal voltage should be measured.†

b. The average value (averaged over one-half cycle) of the control circuit currents flowing as a result of this voltage should be measured.†

3. Any impedance inserted between the external control circuit terminals of the magnetic amplifier and the terminals of the signal voltage source must be specifically described. This impedance, if present, must be the same in all of the tests described in the following.

C. *Output Voltage*

1. For magnetic amplifiers with d-c output, the average value of the output voltage should be measured.*

2. For magnetic amplifiers with a-c output, the output voltage should be measured in the same units as stated in the output rating of the amplifier.

a. For rms output ratings, the output voltage should be measured with a voltmeter which responds to the rms value.‡

b. For average output ratings, the output voltage should be measured with an instrument which responds to the average value.†

c. For ratings based on the fundamental component of the output voltage, the amplitude of the fundamental component should be measured with a wave analyzer.

D. *Output Current*

Output currents should be measured with the same type of instruments as are used to measure the output voltages.

E. *Load*

The amplifier shall be terminated in a resistive load or, if other loads are used, they must be accurately defined.

F. *The Determination of Parameters*

1. Rated output voltage is as specified in ratings.

2. Magnetic amplifier with nonreversible output:

a. Signal voltage should be applied to the control circuit of the magnetic amplifier to determine the minimum output voltage.

b. The maximum test output voltage is defined as the minimum output voltage plus 80% of the difference between the rated and minimum output voltages.

c. The minimum test output voltage is defined as the minimum output voltage plus 20% of the difference between the rated and minimum output voltages.

d. Minimum test and maximum test output currents are defined as those output currents which flow as a result of the corresponding output voltages.

e. Minimum test and maximum test control signal voltages are those control signal voltages required to give the corresponding output voltages.

f. Minimum test and maximum test control signal currents are defined as those control signal currents required to give the corresponding output voltages.

3. Magnetic amplifiers with reversible output.

---

* For example, a D'Arsonval meter movement can be used for steady-state d-c measurements.

† For example, steady-state a-c measurements can be made with instruments having full-wave rectification and D'Arsonval movements. Since these instruments are usually calibrated to measure the rms value of a pure sine wave, the scale reading should be divided by 1.11.

‡ For example, a thermocouple-type voltmeter can be used.

Vol.
Pt. 1
195

a. Positive maximum test output voltage is defined as 80% of the rated output voltage in the positive direction.

b. Negative maximum test output voltage is defined as 80% of the rated output voltage in the negative direction.

c. Positive and negative maximum test output currents are defined as those output currents which flow as a result of the corresponding output voltages.

d. Positive and negative maximum test control signal voltages are defined as those control signal voltages required to give the corresponding output voltages.

e. Positive and negative maximum test control signal currents are defined as those control signal currents required to give the corresponding output voltages.

4. Illustration of parameters:

a. Fig. 1 presents nonreversible parameters.

b. Fig. 2 presents reversible parameters.

II. Voltage Amplification

A. Magnetic Amplifiers with Nonreversible Output

1. The voltage amplification referred to any one control winding is the ratio of the difference between the maximum test output voltage and minimum test output voltage to the absolute value of the algebraic difference between maximum test control signal voltage and minimum test control signal voltage.

$$\frac{\text{max test output V}-\text{min test output V}}{|\text{max test CS V}-\text{min test CS V}|}$$

where V = voltage; CS = control signal.

2. Voltage amplification, as determined by the foregoing, is applicable not only when the control signal and output voltages are both a-c or d-c, but also when one is a-c and the other d-c.

B. Magnetic Amplifiers with Reversible Output

1. The voltage amplification referred to any one control winding is the ratio of the absolute value of the algebraic difference between positive maximum test output voltage and negative maximum test output voltage to the absolute value of the algebraic difference between the positive maximum test control signal voltage and the negative maximum test control signal voltage.

$$\frac{|\text{pm test output V}-\text{nm test output V}|}{|\text{pm test CS V}-\text{nm test CS V}|}$$

where pm = positive maximum; nm = negative maximum.

2. Voltage amplification, as determined by the foregoing, is applicable not only when control and output voltages are both a-c or d-c, but also when one is a-c and the other d-c.

C. Magnetic Amplifiers with Multivalued Control Functions

If, in determining the voltage amplification, it is found that the absolute value of the denominator of the ratio is less than the absolute value of the maximum excursion of the control signal voltage encountered in progressing from one test output voltage to the other, the absolute value of the maximum excursion of control signal voltage shall be used as the denominator.

III. Current Amplification

A. Magnetic Amplifiers with Nonreversible Output

1. The current amplification referred to any one control winding is the ratio of the difference between the maximum test output current and the minimum test output current to the absolute value of the algebraic difference between maximum test control signal current and the minimum test control signal current.

$$\frac{\text{max test o-p}-\text{min test o-p}}{|\text{max test CS current}-\text{min test CS current}|}$$

where o-p = output current.

2. Current amplification as determined by the foregoing, is applicable not only when the control and output currents are both a-c or d-c, but also when one is a-c and the other d-c.

B. Magnetic Amplifiers with Reversible Output

1. The current amplification referred to any one control winding is the ratio of the absolute value of the algebraic difference between the positive maximum test output current and the negative maximum test output current to the absolute value of the algebraic difference between the positive maximum test control signal current and the negative maximum test control signal current.

$$\frac{|\text{pm test o-p}-\text{nm test o-p}|}{|\text{pm test CS current}-\text{nm test CS current}|}$$

2. Current amplification as determined by the foregoing is applicable not only when the control and output currents are both a-c or d-c, but also when one is a-c and the other is d-c.

C. Magnetic Amplifiers with Multivalued Control Functions

If, in determining the current amplification, it is found that the absolute value of the denominator of the ratio is less than the absolute value of the maximum excursion of the control signal current encountered in progressing from one test output current to the other, the absolute value of the maximum excursion of the control signal current shall be used as the denominator.

IV. Power Amplification

The power amplification is the product of the voltage and current amplification when measured under identical operating conditions in accordance with sections II and III.

V. Response Time

A. Control Signals

The magnitude of the control signal must be the difference between the maximum test control signal and the minimum test control signal in the case of a magnetic amplifier with nonreversible output, or the absolute value of the algebraic difference between the positive maximum test control signal and the negative maximum test control signal in the case of a magnetic amplifier with reversible output.

B. Measurements

1. Determine the time (preferably in seconds; it may also be measured in cycles of the power frequency) required after application of the step-function signal for the output quantity to change by an amount equal to 63% (unless otherwise specified) of the final change in output.§ The response time shall be specified as the maximum obtained including such effects as growth or decay, and time phase of signal application.

2. The response time may also be obtained graphically or analytically from the frequency response; see section VI.

---

§ Because of the distorted output waveform obtained from magnetic amplifiers, special means are required to measure the time variation of the output quantity.

A. For magnetic amplifiers with rectified output, the time variation in the average output quantity may be measured in one of the following methods: 1. By using a cyclic integrator to measure the average value of each output half-cycle.[4] 2. By measuring the variation in the firing angle, with the use of oscillographic methods, and determining the variation in the output quantity by conversion factors derived from either steady-state measurements or analytical expressions.[5] 3. By using a suitable low-pass filter to suppress the supply frequency and its harmonics prior to oscillographic measurement. This method is applicable to magnetic amplifiers with relatively slow response (several cycles of the supply frequency).

B. For magnetic amplifiers with a-c output, the output quantity should be rectified and the average response determined as for a d-c output circuit. The average response can then be converted to either rms response or fundamental response by steady-state conversion factors.

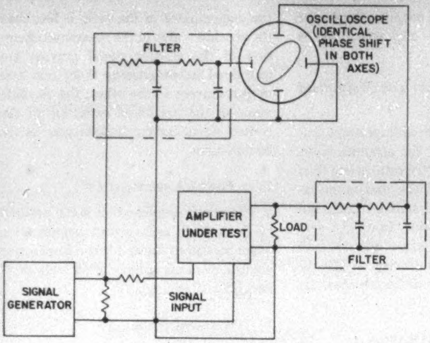

Fig. 3. Frequency response test circuit

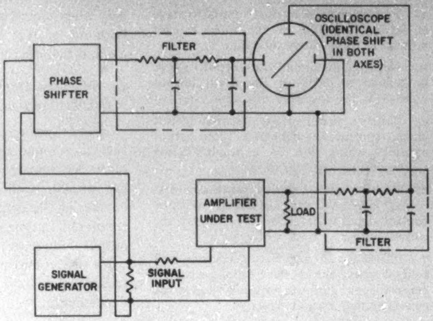

Fig. 4. Frequency response test circuit with phase-shifter

VI. Frequency Response: Amplification and Phase Versus Frequency

A. *Control Signals*

1. The control signals may be in the form of a low-frequency alternating current or in the form of modulation on a carrier. The modulating signal frequency should not exceed 25% of the amplifier's power supply frequency. This practical limit will ensure that the errors inherent in this method of measurement do not become too great.

2. The control signal amplitude should be held constant as the modulating frequency is varied. The control signal amplitude should be specified.

3. If the response time is to be determined graphically or analytically from the frequency response, the magnitude of the control signal must be the difference between the maximum test control signal and the minimum test control signal (measured with the signal frequency equal to zero) in the case of a magnetic amplifier with nonreversible output, or the absolute value of the algebraic difference between the positive maximum test control signal and the negative maximum test control signal (measured with the signal frequency equal to zero) in the case of a magnetic amplifier with reversible output.

B. *Measurements*

Determine the voltage or current amplification and the phase shift through the amplifier as a function of the modulating frequency.[‖]

C. *Presentation of Data*

Data may be presented by one or more of the following methods or their equivalents:

1. Graphing amplifier amplification and phase response versus modulating signal frequency.

2. Expressing the amplifier's performance using LaPlace or similar transforms.[¶]

VII. Figure of Merit

The figure of merit is the ratio of power amplification to the response time (preferably expressed in seconds) when measured under identical operating conditions in accordance with sections IV and V.

[‖] Magnetic amplifier output waveforms are distorted, and special means are required for proper measurements under dynamic conditions. Typical methods are shown in Figs. 3 and 4:

A. The d-c output from the amplifier (demodulation required for a-c carrier output) should be passed through a low-pass filter connected to the input terminals of an oscilloscope. The filter should suppress the carrier frequency and harmonics with as little disturbance to the signal frequency as possible.

B. The control signal should be applied through an identical filter to the other input of the oscilloscope. Demodulators will be required for carrier-type control signals. If a nulling method is used, as in Fig. 4, a phase shifter is required at the control signal source.

[¶] A transfer function of the following type may be obtained by "curve fitting" from the graphs referred to in paragraph 1 of section VI C. Such a linear transfer function is a very close approximation at signal frequencies which are well below the amplifier's power supply frequency:

$$G(s) = \left[\frac{K_1 e^{-st_1}}{1+T_1 s}\right]\left[\frac{K_2 e^{-st_2}}{1+T_2 s}\right]\cdots\left[\frac{K_n e^{-st_n}}{1+T_n s}\right]$$

where n = number of stages of amplification, t = dead time, and T = time constant. For a more rigorous mathematical treatment of transfer functions as applied to a pulse output device such as a magnetic amplifier, see references 6, 7, and 8.

Long Time Delays From a Single Magnetic Storage Core

C. E. HARDIES
ASSOCIATE MEMBER AIEE

ACCURATE time delay devices are essential to both industrial and military control applications. Static time delay devices presently available provide time delays accurately and economically up to a few seconds. The emphasis on reliability in the industrial and military control fields has made it desirable that a static device be developed to generate the long time intervals required in these areas where reliability and accuracy are so fundamentally important.

This paper describes the theory and circuitry of a device which produces long time delay. It uses magnetic cores with essentially rectangular hysteresis loops, as idealized in Fig. 1, and transistors as switches. Accuracies of better than one per cent are achieved for time intervals less than 1/10 second up to several minutes. The device can be used in conjunction with static switching devices in performing the functions of logic for control purposes.

Some of the basic properties of the magnetic cores used in this device have been utilized in other circuit applications, and many effects other than amplification have been achieved. Dr. H. F. Storm[1] has written an excellent article summarizing some of the circuit applications. The property of a rectangular-loop magnetic core to absorb a fixed volt-second integral as determined by the flux change from one saturation level to the other has been used in short time delays by G. F. Pittman,[2] J. L. Lowrance,[3] R. L. Van Allen,[4] and others. The present device uses this basic integrating property in such a way that the time delays which can be achieved in a single stage are much longer than in previous devices. While time delays less than 1/10 second can be generated in the circuit, this device will have its main usefulness in the generation of long time intervals.

In this connection, another type of static timing device should be mentioned. These are based on resistance-capacitance (R-C) time constants. The use of R-C devices for short time delays offers an inexpensive, accurate device. To achieve accuracy for long time delays, the basic R-C device must be modified to such a degree that the advantage of its simplicity is lost.

In the device described by Pittman, this fixed volt-second value is used to advantage. By pulsing the magnetic core with unidirectional pulses of fixed volt-seconds, the core flux is changed from $-\Phi_s$ to $+\Phi_s$ in discrete steps as shown in Fig. 2. The time delay is determined by the rate and number of these volt-second pulses. This can be expressed as follows: where n is the number of pulses, N is the number of turns, Φ_s is the saturation flux density in lines, e is the the instantaneous value of of the core voltage applied for the time interval Δt.

$$n=\frac{2N\Phi_s}{\int_{\Delta t} e dt}\times 10^{-8} \qquad (1)$$

The present device extends this basic reasoning to include the proposition that this voltage function need not be unidirectional. Time delays are achieved by alternately pulsing the core with positive and negative volt-second pulses. The difference between the positive and negative pulses is adjusted to be a few microvolt-seconds. The time interval which can be generated is determined by the number of times this difference must be applied to the core in order to change the flux level from one saturation to the other. The number of full cycles which must be applied to the core to accomplish this flux change can be expressed:

$$n=\frac{2N\Phi_s}{\text{(difference volt-seconds)}} \qquad (2)$$

The smaller the difference between the positive and negative pulses, the greater the values of n. Experimentally, it is not difficult to achieve values of n in excess of 7,000 with a single storage core. Since this number can be made so large, the pulses can be taken directly from a 60-cycle power source with time delays of 2 minutes using a single magnetic core. Using unidirectional pulses, four stages would be required to produce an equivalent time interval.

There are other advantages gained using the reversing polarity pulses:

1. The circuitry can be symmetrical, thus minimizing the effects of temperature, voltage, and frequency. The idealized hysteresis loop in Fig. 1 shows a constant magnetizing current, however, an actual hysteresis loop for a practical core will show a magnetizing current which varies as the core flux level is changed. Symmetrical operation will minimize the effects of this variation.

2. Another effect of magnetizing current which can affect the accuracy of these timing circuits is the volts-per-turn dependency of such currents. By symmetrical operation the error caused by volt-per-turn changes is almost eliminated.

3. It is possible to supply the device directly from the 60-cycle power source. This eliminates the need for special pulse forming circuits or low frequency generators.

Basic Circuitry

The basic theory of the device requires that the voltages applied to the core on alternate half cycles of the power source be unequal. This can be achieved in at least three ways: a current control, a volt-

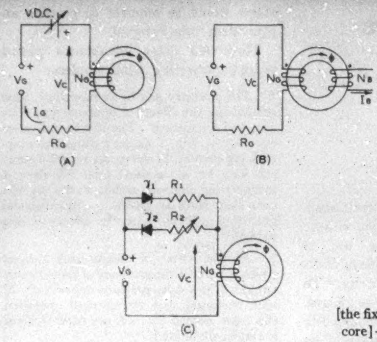

Fig. 3 (left). Basic timing circuits

A—D-c voltage control
B—D-c current control
C—Resistive control

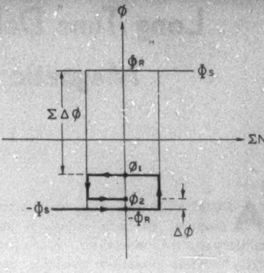

Fig. 4 (right). Flux changes with assymmetric bidirectional pulses

age control, or a resistive control. The effect of this control is the same in all three, making it possible for combinations to be used in the same application. Basic circuits for the three methods are shown in Fig. 3. Each of the three will be described briefly, and then a method by which delayed positive feedback can be used to provide the necessary output level for each.

Fig. 3(A) shows a circuit where a d-c voltage is used to produce and control the assymmetry of the core voltage. The core voltage, V_c, can be expressed as follows:

$$V_c = \hat{V}_g \sin \omega t + V_{\text{d-c}} = R_g I_g \tag{3}$$

The net flux change per cycle will be:

$$\phi \text{ per cycle} = \frac{10^8}{N} \int_{\Delta t} V_c dt \tag{4}$$

The fixed volt-second intergal of the core for a flux change from one saturation level to the other is:

$$n \int_{\Delta t} V_c dt = 2N\Phi_s \times 10^{-8} \tag{5}$$

The number of cycles of operation of the circuit of Fig. 3(A) which will cause a flux change from $-\Phi_s$ to $+\Phi_s$ can be expressed:

$$n = \frac{2N\Phi_s}{\int_{\Delta t} V_c dt} \times 10^{-8} \tag{6}$$

Since saturation will occur when the flux level reaches $+\Phi_s$, the actual flux change which must be accomplished by the difference volt-seconds will be the fixed volt-second integral of the core less the volt-second integral of the positive pulse. This is illustrated in Fig. 4. A discreet number of flux increments, $\Sigma\Delta\Phi$, is required to change the flux level from its value at the end of the first half cycle to $+\Phi_s$. This can be expressed as follows:

$$n = \frac{\text{[the fixed volt-second integral of the core]} - \text{[volt-second integral of the positive half cycle of the core voltage]}}{\text{[full cycle net volt-second integral of the core voltage]}} \tag{7}$$

$$n = \frac{2N\Phi_s \times 10^{-8} - \int_0^{\pi} (\hat{V}_g \sin \omega t + V_{\text{d-c}} - R_g I_g) dt}{\int_0^{2\pi} (\hat{V}_g \sin \omega t + V_{\text{d-c}} - R_g I_g) dt} \tag{8}$$

The value of n can be found readily if I_g is known as a function of time. This value of I_g will be dictated by the hysteresis loop assumption. If the voltage drop $R_g I_g$ is several orders of magnitude less than V_g, then the magnitude of I_g can be assumed equal to I_m of the assumed loop over the entire half cycle. With loops as displayed by Orthonol (50–50 nickel-iron alloy) cores, the symmetrical operation of the circuit will permit the use of an average value for I_m and thus, a constant value of I_g over the entire half cycle.

Integration of equation 8 yields:

$$n = \frac{2N\Phi_s \times 10^{-8} - \frac{2\hat{V}_g}{\omega} + (V_{\text{d-c}} - R_g I_g) \frac{\Delta t}{2}}{V_{\text{d-c}}(\Delta t)} \tag{9}$$

This can be converted to time delay for a 60-cycle-per-second frequency.

$$T = \frac{2N\Phi_s \times 10^{-8} - \frac{2\hat{V}_g}{\omega} + (V_{\text{d-c}} - R_g I_g) \frac{\Delta t}{2}}{V_{\text{d-c}}} \tag{10}$$

where $\Delta t = 1/60$ and $\omega = 377$.

As seen by equation 10, the delay time is dependent on voltage and frequency. By using a core and number of turns which will make the fixed volt-second integral of the core 20 times the volt-second integral of the positive volt-second-pulse, accuracy of one per cent will be achieved for a combined voltage and frequency change of ±10% each. A 20 to 1 relationship between the fixed volt-second integral of the core and the volt-second integral of the positive half cycle is easily achieved in practice. Experimental results are given using this ratio.

Fig. 3(B) shows a circuit which uses a d-c bias on the core to produce the assymmetrical core voltage. In this circuit configuration the core is biased to a magnetomotive force by the applied bias current I_B. This will cause the primary current I_g to assume different values on positive and negative half cycles and thus, a different $R_g I_g$ voltage drop. The expression for n, the number of cycles of operation before saturation in this case, can be expressed by equation 7. Substitution into this equation yields:

$$n = \frac{2N\Phi_s \times 10^{-8} - \int_0^{\pi} (\hat{V}_g \sin \omega t - R_g I_g) dt}{\int_0^{\pi} (\hat{V}_g \sin \omega t - R_g I_g) dt + \int_{\pi}^{2\pi} (\hat{V}_g \sin \omega t - R_g I_g) dt} \tag{11}$$

The value of I_g can be expressed, as shown in Fig. 5, by

$$I_g]_{0\,\mathrm{TO}\,\pi} = I_m - I_B \left(\frac{N_B}{N_G} \right) \tag{12}$$

$$I_g]_{\pi\,\mathrm{TO}\,2\pi} = I_m + I_B \left(\frac{N_B}{N_G} \right) \tag{13}$$

where $I_g R_g$ is again several orders of magnitude less than $\hat{V}_g$.

Integration of equation 11 with the values of I_g from equations 12 and 13 yields:

$$n = \frac{2N\Phi_s \times 10^{-8} - \frac{2\hat{V}_g}{\omega} - R_g \left[I_m - I_B \left(\frac{N_B}{N_G} \right) \right] \frac{\Delta t}{2}}{2R_g I_B \left(\frac{N_B}{N_G} \right) \frac{\Delta t}{2}} \tag{14}$$

In terms of time this equation is:

$$T = \frac{2N\Phi_s \times 10^{-8} - \frac{2\hat{V}_g}{\omega} - R_g \left[I_m - I_B \left(\frac{N_B}{N_G} \right) \right] \frac{\Delta t}{2}}{R_g I_B \left(\frac{N_B}{N_G} \right)} \tag{15}$$

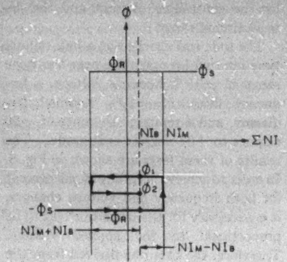

Fig. 5. Flux changes with d-c bias current and symmetrical pulses

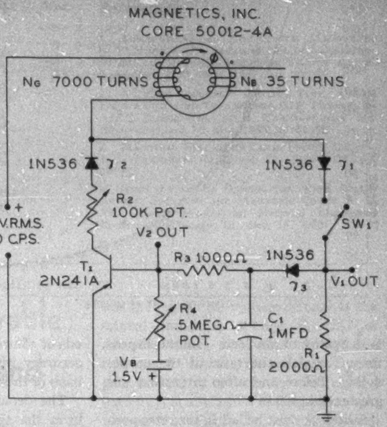

Fig. 6. Single-stage time delay

As in the case of the d-c voltage control, a 20 to 1 ratio must exist between the fixed volt-second integral of the core and the volt-second integral of the positive half cycle in order to maintain one percent accuracy for combined voltage and frequency variations of ±10% each.

In Fig. 3(C) a method of control is shown where the core voltage assymmetry is produced and controlled by resistive means. If the rectifiers γ1 and γ2 are assumed perfect, then the resistive voltage drop on the positive half cycles of the applied voltage will be R_1I_g, and on the negative half cycle R_2I_g. The net volt-second difference will be:

$$\int_0^{\pi} (\hat{V}_g \sin \omega t - R_1 I_g)dt + \int_{\pi}^{2\pi} (\hat{V}_g \sin \omega t - R_2 I_g)dt \quad (16)$$

Assymmetry is produced by the difference between the values of R_1 and R_2. The time in seconds is:

$$T = \frac{2N\Phi_s \times 10^{-8} - \frac{2\hat{V}_g}{\omega} - R_1 I_g\left(\frac{\Delta t}{2}\right)}{\frac{(R_2 - R_1)I_g}{2}} \quad (17)$$

Again, the 20 to 1 ratio between the fixed volt-second integral of the core and the volt-second integral of the positive half cycle must be maintained for one percent accuracy with a combined frequency and voltage variation of ±10% each.

Comparison between equations 10, 15, and 17 shows that all three will produce a similar characteristic, delay time versus direct voltage, direct current, or resistance. Any of the three methods can be used to establish the delay time.

In all of the cases just described, saturation is indicated at the end of the time interval by a sharp increase in the voltage drop across the series resistor. This voltage drop occurs near the end of the half cycle and does not represent much power. High output power is achieved by removing the negative half cycle once saturation is indicated. This will cause the core to self-saturate. A transistor circuit can be used for this purpose.

The circuit of Fig. 6 shows a circuit using resistive control, with a transistor for attaining output power. If resistors R_1 and R_2 are made equal, any of the control methods can be used. The transistor, T_1, of Fig. 6 is biased normally in its "on" or short circuit condition. This bias is somewhat less than the voltage across R_1 after saturation occurs. The diode γ_3 is provided to transfer the voltage across R_1 to the R-C network R_3 and C_1. The resistor R_3 is used for protection of the transistor's base. The capacitor C_1 provides a phase shift between the voltage R_1I_g and the voltage which appears across the base to emitter terminals of the transistor, T_1. This must be sufficient to hold the transistor open-circuited during some part of the succeeding half cycle. If this is achieved, the core will have a smaller volt-second reset during this half cycle and the output in the next positive half cycle across R_1 will increase. This "avalanche" action will continue until the transistor is held open circuit for the entire negative half cycle and the core is self-saturated. Very little voltage will be absorbed by the core, and the output will be half-wave rectified.

This avalanche or delayed positive feedback can take many cycles of the excitation before full output is achieved. The amount of time required can be used to compensate the device for inaccuracy due to temperature since the number of cycles during avalanche is a function of the bias on the transistor. An increase of temperatures on the core shortens time delays, while the same temperature change on the transistor lengthens them to a greater degree. These effects tend to self-compensate, but the bias supply to the transistor must still be temperature compensated to achieve the required accuracy.

The output of the device has been described as half-wave rectified across resistor R_1. Across the capacitor C_1, there exists a filtered d-c which is essentially the peak value of the rectified voltage across R_1. This may also be used for output. Approximately 1/2 watt can be delivered by the device. This can be used to drive a power switching device such as a transistor, magnetic amplifier, vacuum-tube amplifier, high-impedance relay, or the recently developed solid-state thyratron.

The circuit shown in Fig. 6 uses a p-n-p transistor for the delayed positive feedback. The polarity of the output is negative to the ground as shown in the figure. By reversing the diodes γ_1, γ_2, and γ_3 and using an n-p-n transistor for avalanche, the polarity of the output can be reversed. The output would then be positive to the ground as shown. This would facilitate the use of p-n-p power transistors or other output devices requiring this polarity signal.

The switch, S_1 in Fig. 6 is used to reset the core to its $-\Phi_s$ level after the timing interval. When switch S_1 is open, only those half cycles of the applied voltage, V_g are applied to the core which provide negative or resetting volt-seconds. When S_1 is open the output is zero. Closure of S_1 initiates the timing cycle. While this is taking place, the voltage across resistor R_1 and capacitor C_1 is very low. After saturation and avalanche, the voltage across these points rises, and output

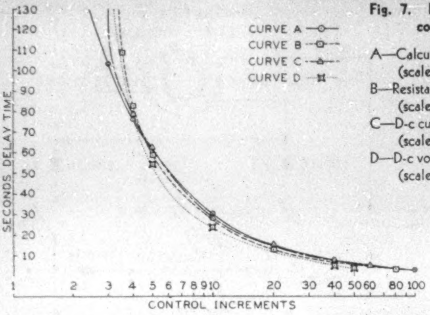

Fig. 7. Delay in second versus control increments

A—Calculated (scale × 0.01 = d-c volts)
B—Resistance controlled (scale × 100 = [$R_2 - R_1$] ohms)
C—D-c current controlled (scale × 1 = milliamperes)
D—D-c volts controlled (scale × 0.01 = d-c volts)

is delivered to the load. In the experimental models the ratio of the output voltage before and after saturation was greater than 100 to 1.

Switch S_1 must be left in the reset position for enough cycles to allow the core flux to be completely reset to its $-\Phi_s$ level before the device can be recycled. This will amount to 20 cycles if the ratio between core fixed volt-second capacity and applied half-cycle volt-seconds is maintained at 20 to 1 as previously determined.

The device could be used for purposes other than time delay. It could be a frequency divider if a transistor replaced switch, S_1, and a bistable device is used to drive this transistor. Signal for the bistable device can be taken from a resistor in series with the magnetic core. The voltage drop across this resistor is essentially zero during timing intervals and has the same polarity as the voltage across R_1 after the timing cycle. During reset it is again essentially zero and after the core has been reset, it has the opposite polarity as at the end of the timing cycle.

The high sensitivity of the device at long time intervals suggests its application in converting low-level analog signals to frequency. The core storage capacity could be designed in order to achieve high sensitivity for any desired frequency range.

Experimental Results

The operation of the timer circuit of Fig. 6 was experimentally checked for all three methods of establishing time intervals. These plots are shown together with the theoretical characteristic plot for the timer. As previously noted, this characteristic plot is common to all three methods of control. The scale for the independent variables was determined by use of equations 10, 15, and 17. The similarity of the plots shows the feasibility of combining the different methods of control in the same device and the accuracy which can be predicted on the basis of these equations.

The departure at long time intervals from the theoretical curve was caused by the transistor. When the curves were plotted without this transistor, and thus without sufficient output, the experimental curves followed the calculated one quite closely. The use of the transistor circuitry has permitted an output power level which can be utilized to drive switching devices. Its inclusion, however, has introduced difficulties in making a device which is continuously variable over the entire delay range while maintaining high accuracy.

Several sources of error were discovered while the experimental plots of Fig. 7 were being made. The error in reproducing readings of a given interval was approximately 0.5%. Several readings were taken of each time interval, and averaged to minimize this 0.5% error.

The d-c current method of setting time intervals was found to deviate considerably from the predicted curve for large control currents. Actually the current bias could only be plotted to 25 milliamperes. It was found that the bias ampere turns became equal to the magnetizing current ampere-turns at this level, and the core flux could be changed due to the bias ampere-turns alone.

The plots of Fig. 7 indicate that a given core volt-second capacity will provide a given range of delay times. The range for the magnetic core used in the experimental model extends from approximately 5 seconds to 100 seconds since, for times in excess of 100 seconds, the adjustment of the control becomes quite critical. In order to make the device less sensitive to control changes, the core volt-second capacity could be increased or two cores placed in series. The choice of core volt-second capacity must be made in view of both the sensitivity required by the controlling element and the desired timing range.

The unit was checked at a half minute time interval for operation over a voltage range of ±10% nominal voltage, a frequency range of ±10% nominal frequency, and a temperature range of −20 degrees to +60 degrees centigrade. The results of these tests are shown in Fig. 8. In order to achieve accuracy of one percent for both frequency and voltage changes, it is necessary for the transistor bias to be proportional to the applied voltage. Therefore, the bias was derived from the a-c excitation to obtain the accuracies shown in Fig. 8. The device was subjected to both shock and vibration in an effort to determine the effect on the timing interval. Preliminary results show the effects of vibration and shock will be small. Quantitative results were not available.

Conclusions

Time delays up to several minutes can be accurately generated in a single stage utilizing solid state components only. Experimental models have been built which will provide specific time delays up to 2 minutes with accuracy better than one per cent.

Effects other than time delay can be realized using this circuitry; for example, counting, frequency division, analog signal to time, or analog signal to frequency.

The signal required for the device can be: a d-c voltage, a d-c current, a change of resistance, or a combination of these.

The number of counts which can be

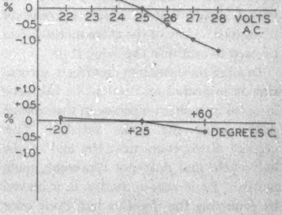

Fig. 8. Per-cent accuracy versus frequency, voltage, and temperature for a fixed 30-second delay

reliably stored in a rectangular hysteresis-loop magnetic core can be predicted using the derived equations.

Large numbers of counts can be stored in a single core by using bidirectional pulses. This use of bidirectional pulses minimizes the problems caused by core characteristics.

Nomenclature

n = number of cycles per time interval
N = turns
$\pm\Phi_s$ = magnetic flux at saturation in Maxwells
e = instantaneous voltage
$\Delta\phi$ = net core flux change per cycle
v_g = peak value of applied sinsuoidal voltage
$V_{d\text{-}c}$ = d-c control voltage
R_g = lumped gate circuit resistance
I_g = average gate current
Δt = period of one full cycle
N_G = gate windings
N_B = bias windings
I_B = average bias current
I_m = average magnetizing current
$V_{1\,\text{out}}$ = full-wave rectified output
$V_{2\,\text{out}}$ = filtered d-c output

Synopsis: A series-connected saturable reactor with capacitive loading exhibits interesting features. The circuit may exhibit instability associated with a double or three-valued output corresponding to a given input depending on previous history of operation. In some ranges of circuit parameters and forcing function, the circuit may become regenerative thus oscillating at a low frequency modulating the carrier.

A brief survey of the different phenomena occurring in the circuit is given in the first part of this paper. The rest of the paper is devoted to a thorough analysis of the oscillatory feature of the circuit. Assuming a rectangular forcing function, the critical conditions for oscillation and the frequencies at which the circuit oscillates are derived.

Since a saturable reactor essentially responds to the half-cycle average input, it may be expected that the theoretical results obtained for the case of a rectangular forcing function predict approximately the behavior of the circuit for the case of sinusoidal excitations. A comparison of measured results obtained from a circuit excited by a sinusoidal voltage with the theoretical results deduced in this paper show good correlation.

A REVIEW of the literature indicates that very little work has been done concerning the operation of magnetic amplifiers with capacitive loading. Addition of capacitance to magnetic amplifier circuits, modifies their modes of operation, and adds to the complexity of the analysis involved due to discontinuities in current or jump phenomena and low-frequency oscillations.

A practical investigation of common magnetic amplifier circuits with capacitive loading reveals interesting behavior, particularly the series-connected saturable reactor circuit shown in Fig. 1. This circuit consists of two identical reactors with primary and secondary windings, which are connected in such a way that a voltage applied to the two primary (gate) windings in series produces zero current in the secondary (control) winding as indicated by the polarity marks. The behavior of the circuit changes appreciably with the amount of resistance in the control circuit. Thus it is convenient to divide the operation into two cases of infinite and finite control impedance as follows.

Infinite Control Impedance. Assuming a sinusoidal gate voltage, the steady-state analysis of a series-connected saturable reactor with capacitive loading and infinite control impedance is given in reference 1. The behavior of the circuit is described by the nondimensional control characteristics of Figs. 2(A) and (B). The characteristics of Fig. 2(A), relating the nondimensional control current $R_g\bar{I}_c/\sqrt{2}E$ to the nondimensional gate current $R_gI_g/\sqrt{2}E$, are applicable when the nondimensional gate voltage $E/AB_cN_g\omega$ is less than a critical voltage defined as the critical transition voltage $E_t/AB_cN_g\omega$. At such values of applied voltage the relationship between the average value of gate current I_g and the referred control current I_c is a function of the phase angle ($\phi=\tan^{-1} 1/\omega CR_g$) only. Thus assuming a phase angle of 80 degrees, it may be seen from Fig. 2(A) that as the control current is increased from zero the average value of gate current increases linearly along the line OM. At M the gate current reaches its maximum value where, if the control current is further increased, the gate current drops abruptly to A_1 and remains at a constant value for further increase in control current. However, if the control current is reduced the gate current maintains its constant value only until the point C_1 is reached then it increases smoothly to the point D_1 where for further decrease in control current the gate current jumps to the point E_1. Then the relationship is again linear as described by the line OM, so that if the control current is increased the gate current increases linearly to M. Then it repeats the previous cycle. But if the control current is reduced, the gate current reduces linearly to zero. For $\phi=70$, 60, 50, and 40 degrees, the same sort of operation occurs. Thus for $\phi=70$ the operation is described by the path $OHA_2C_2D_2$-E_2O. The bistable operation disappears at a theoretical value of phase angle of 32.5 degrees. For phase angles less than this value the operation is reversible as seen from the curves corresponding to $\phi=0$, 10, 20, and 30 degrees, where the deviation from the linear relationship occurs before the point M is reached, that is, at the

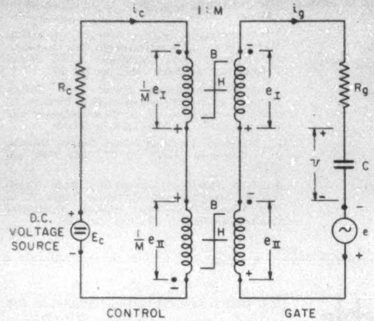

Fig. 1. Idealized series-connected saturable-reactor circuit with capacitive loading and finite control resistance having ideal reactors of zero-winding resistance and the magnetization characteristic of Fig. 5

points P_9, P_8, P_7, and P_6, respectively. For $\phi=0$, corresponding to the case of resistive loading discussed in reference 2, the control characteristic is described by the path OP_9QR.

When the value of the nondimensional applied voltage $E/AB_cN_g\omega$ exceeds the critical transition voltage, the control characteristics become a function of both the phase angle and the applied voltage. The control characteristics corresponding to a phase angle of 70 degrees are given in Fig. 2(B). The value of the critical transition voltage $E_t'/AB_cN_g\omega$ at this value of phase angle is given as 0.61. Thus for $E/AB_cN_g\omega=1.11$, which exceeds the critical transition voltage, examination of Fig. 2(B) shows that as the control current is increased from zero, the average value of gate current increases linearly from zero along the line OM up to the point B_3, where the current suddenly jumps to C_3. If the control current is then reduced the operation is along the path $C_3S_3A_3O$, while if the control current is increased the operation is along the path C_3D_3. At D_3 the gate current suddenly drops to the point E_3, where for further increase of control current the gate current remains constant as indicated by the horizontal line E_3L. However, if the control current is reduced the gate current remains constant only until the point F is reached, then it rises to the point G smoothly. When G is reached, the gate current rises abruptly to the point J_3, where, if the value of control current is reduced, the operation is described by the path J_3C_3-S_3A_3O; while if the control current is increased the path $J_3D_3E_3L$ is followed. The same sort of operation occurs for $E/AB_cN_g\omega=0.91$, as seen from the

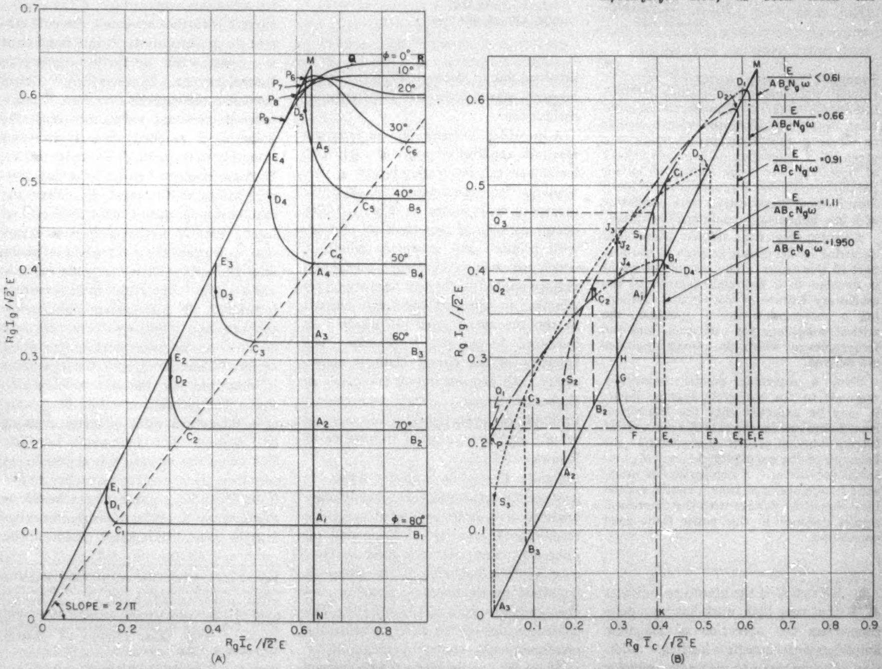

Fig. 2. Control characteristic of the series-connected saturable reactor of Fig. 1 supplied with a sinusoidal gate voltage and controlled by a d-c soucre, for values of applied voltage smaller (A), and larger (B), than the critical transition voltage defined in reference 1

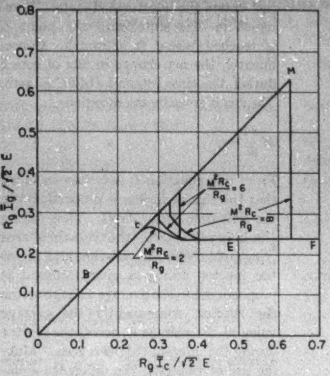

Fig. 3. Measured relationship between gate and control current taken at three fixed values of $M^2R_c/R_g=\infty$, 6, and 2, for the series-connected saturable reactor of Fig. 10 using two reactors of Fig. 4 supplied from a sinusoidal gate voltage and controlled by a voltage source. In these three cases ϕ was adjusted to a fixed value of 70 degrees. The case of infinite-control impedance was approximated by inserting a high inductance in series with the control windings. For $M^2R_c/R_g=6$ and 2, the corresponding values of R_c were 2,400 and 800 ohms, respectively, $E=40$ volts, $f=60$ cps

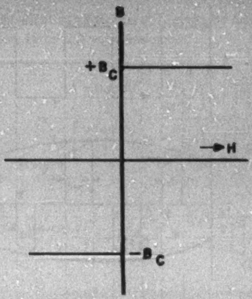

Fig. 5. Assumed ideal magnetization characteristic

corresponding curve of Fig. 2(B). However, for $E/AB_cN_g\omega=0.66$ the operation differs slightly from the previous cases, since there is not point corresponding to J_3 and J_2. Thus, when the point G is reached, the gate current shows only a small jump to the point H, where the relationship between the gate and control current becomes linear. Also for $E/AB_cN_g\omega=0.66$, the vertical line C_1B_1 is to the right of the point H, consequently for a given value of control current corresponding to the point K, the gate current might take one of the three possible values Q_1, Q_2, or Q_3 depending on the history of operation memorized by the circuit. For the other curves there are only two possible values of gate current for a given value of control current.

When values of $E/AB_cN_g\omega$ exceed a second critical voltage defined as the critical extinction voltage $E_c'/AB_cN_g\omega$ the behavior is different in that the gate current does not reduce to zero as the control current is reduced. The value of the critical extinction voltage is larger than the critical transition voltage, and is a function of the phase angle. For example the value of the critical extinction voltage $E_c'/AB_cN_g\omega$ at a phase angle of 70 degrees is about 1.14. Thus for $E/AB_cN_g\omega=1.950$, which exceeds the critical extinction voltage, the behavior is described by the path $PD_4E_4FGJ_4P$, shown in Fig. 2(B). Consequently, for magnetic amplifiers with capacitive loading, a condition of normal or under excitation may be defined corresponding to the case of resistive loading[2] by restricting the magnitude of the applied voltage to a value less than the critical extinction voltage.

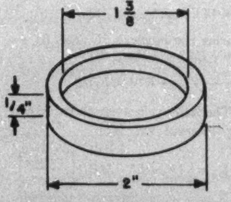

Fig. 4. Core of two identical experimental Deltamax reactors composed of 0.001-inch tape. Each wound with two windings; winding A: 5,000 turns of no. 33 wire gage, 145 ohms resistance, used as gate winding of the series-connected saturable reactor; winding B: 5,000 turns of no. 33 wire gage, 190 ohms resistance, used as the control winding of series-connected saturable reactor

Finite Control Resistance. The effect of control resistance on the steady-state behavior of a series-connected saturable reactor with capacitive loading may be seen from the measured relationship of Fig. 3. The relationships given correspond to three values of control resistances $M^2R_c/R_g=2$, 6, and ∞ respectively at a fixed phase angle of 70 degrees. This shows that as the control resistance is reduced, the bistable behavior of the circuit becomes less marked and disappears when the control resistance is sufficiently reduced, such as $M^2R_c/R_g=2$, where the operation is described by a single value curve *OBCEF*.

Further investigation of the circuit for the case of finite control impedance indicated that at some regions of operation where the d-c transformer law holds (indicated by the line *OM* of Fig. 3), the circuit may become regenerative. Thus, at low values of control voltage compared to the referred gate voltage as indicated by the region *OB*, the circuit oscillates at a frequency lower than the carrier frequency. The frequency of oscillation depends on the value of resistance present in the circuit. The oscillatory behavior of the circuit may be predicted from the dynamic analysis of the circuit.

An attempt to extend the steady-state analysis given in reference 1 for the limiting case of infinite control impedance to the more general cases of finite control resistance and dynamic behavior will be extremely laborious if not impossible. This difficulty may be avoided by assuming a rectangular instead of a sinusoidal excitation. The results derived in this paper on the basis of such an assumption confirms the possibility of the existence of a low-frequency oscillation. The frequency of oscillation and the condition for such oscillations is derived. The results derived on the basis of rectangular excitation predict the behavior of the circuit for the case of sinusoidal excitation approximately. This is true since a series connected saturable reactor is essentially a device whose operation may be expressed in terms of half-cycle average values of input and output.

Theory and Assumption

The experimental circuit analyzed consists of two identical reactors with Deltamax* cores of rectangular hysteresis loop. Each core is wound with two equal windings of design details shown in Fig. 4. For a reactor using Deltamax or similar core materials, the magnetization current in many applications may be neglected. Thus for the purpose of analysis, an ideal magnetization characteristic of Fig. 5 may be assumed. On the basis of this assumption the experimental circuit may be

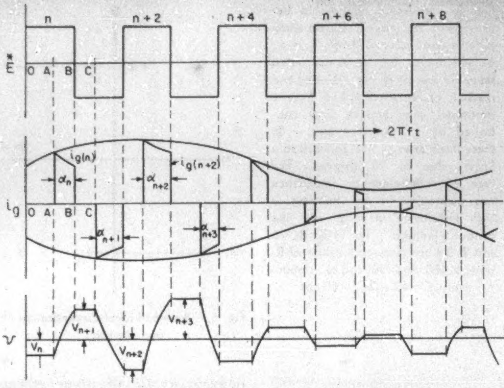

Fig. 6. Waveshape of gate current flowing in idealized series-connected saturable reactor of Fig. 1 and voltage across condenser for rectangular gate excitation and d-c control. Waveshape corresponds to oscillatory case where control voltage is assumed to be below critical value at which sustained oscillation starts

represented by the ideal circuit of Fig. 1, which fulfills the following conditions:

The effective gate resistance R_g is the sum of the two gate-winding resistances and the external gate resistance, $R_g = 2R_{wg} + R_{Lg}$.

The effective control resistance R_c is the sum of the two control-winding resistances and the external control resistance, $R_c = R_{wc} + R_{Lc}$.

The inductance of the core is either zero or infinity.

Hysteresis and eddy-current losses are negligible.

The distributed and winding capacitance of the reactor is negligible, and the leakage of the load condenser is negligible.

Assuming a rectangular gate voltage and a d-c control voltage, the ideal circuit is analyzed. The theoretical results deduced are compared with measured results obtained from the experimental circuit. The correlation between theoretical and measured results confirms the validity of the idealized assumptions made.

Modes of Operation and Circuit Equations

Let a rectangular gate voltage of constant amplitude be applied to the circuit of Fig. 1. In the linear region of operation where d-c transformer law holds as described by line *OM* of Fig. 3, the resulting current pulses and the voltage across the condenser are shown in Fig. 6, where α, V, i_g, and I_g denote the conduction angle, constant voltage across the condenser during nonconduction intervals, instantaneous value of gate current, and the half-cyclic average value of the gate current, respectively. It is assumed that the reader has some basic knowledge regarding the behavior and the mechanics of operation of the circuit for the case of pure resistive loading. This is necessary to understand the subsequent analysis given. For this purpose reading of reference 3, dealing partly with the dynamic behavior of a series-connected saturable reactor with resistive loading, is recommended. For the case of capacitive loading, the mechanics of circuit operation corresponding to the direction of current and voltage indicated in Figs. 1 and 6 is as follows:

During the flow of negative current pulses, reactor I is saturated while reactor II is unsaturated.

During the flow of positive current pulses, reactor I is unsaturated while reactor II is saturated.

During the nonconduction intervals, both reactors are unsaturated.

For these possible modes of operation, it may be concluded that the gate current is a transformation current equal to the value of control current referred to the gate side. The behavior of the circuit may be determined in terms of three unknowns, α, V, and I_g, already defined. Consequently three difference equations are required. These equations may be derived as follows.

Equation I. The first equation may be obtained from consideration of the flux change in core I. At the point O, core I just enters the unsaturated state. It remains in this state until the point *C* is reached where it saturates. Consequently, the net change in flux of core I during the time interval *OABC* is zero. The flux is given by the equation

$$M\frac{d\Phi}{dt} = e_I$$

From this equation it may be concluded that the change in flux is proportional to the volt-time area $\int e_I dt$. Thus during the interval *OABC*, the volt-time area $\int e_I dt = 0$. Since the volt-time area across the reactor during a given interval is proportional to the average voltage across the reactor, consequently the average value of the voltage e_I, across the reactor during the interval *OABC* is zero. Making use of this fact, the difference equation may be obtained as follows.

During the interval *OA*, both reactors are unsaturated, thus it may be shown that

$$e_I = \frac{1}{2}\left[V_n + E^* - ME_c\right] \tag{1}$$

Note: During the intervals when both cores are unsaturated (such as *OA* and *BC* of Fig. 6), the behavior of the circuit is described by the following equations, which may be obtained by applying Kirchhoff's and Ampere's laws to the circuit which gives:

$$e_c = R_c i_c + e_{II}/M - e_I/M \tag{1A}$$

$$e = R_g i_g + v + e_I + e_{II} \tag{1B}$$

$$Mi_g = i_c \tag{1C}$$

$$Mi_g = -i_c \tag{1D}$$

From equations 1(C) and 1(D) it may be seen that $i_c = i_g = 0$. Substituting this condition in equations 1(A) and 1(B) and solving for e_I, gives:

$$e_I = (e - Me_c - V)/2$$

During the interval *OA* (Fig. 6), $e = +E^*$, $e_c = +E$, $v_c = -V_n$, thus

$$e_I = +(V_n + E^* - ME_c)/2$$

During the interval *BC* (Fig. 6), $e = -E^*$, $e_c = +E_c$, $v = +V_{n+1}$, thus

$$e_I = -(V_{n+1} + E^* + ME_c)/2$$

The half-cycle average value of e_1 during interval *OA* is:

$$[e_I]_{OA} = \frac{1}{2}\left[V_n + E^* - ME_c\right]\left[\frac{\pi - \alpha_n}{\pi}\right] \tag{2}$$

Similarly during the interval *BC* both reactors are unsaturated, thus

$$[e_I] = -\frac{1}{2}\left[V_{n+1} + E^* + ME_c\right]$$

(see note following equation 1) **(3)**

The half-cycle average value of e_I during this interval is:

$$[e_I]_{BC}=-\frac{1}{2}[V_{n+1}+E^*+ME_c]\left[\frac{\pi-\alpha_{n+1}}{\pi}\right] \tag{4}$$

During the interval AB, reactor II is saturated while reactor I is unsaturated, thus it may be shown that:

$$-\frac{1}{M}e_I=E_c-R_ci_c$$

or

$$e_I=M^2R_ci_{g(n)}-ME_c$$

The half-cycle average value of e_I during this interval is given by:

$$[e_I]_{AB}=M^2R_cI_{g(n)}-ME_c\frac{\alpha_n}{\pi} \tag{5}$$

where $I_{g(n)}$ is the half-cycle average value of load current during nth half-cycle. As previously deduced,

$$[e_I]_{OA}+[e_I]_{AB}+[e_I]_{BC}=0$$

Substituting equations 2, 4, and 5 in this equation gives the required difference equation which is of the form:

$$[V_n-V_{n+1}-2ME_c]-[V_n+E^*+ME_c]\times\frac{\alpha_n}{\pi}+[V_{n+1}+E^*+ME_c]\frac{\alpha_{n+1}}{\pi}+2\left[\frac{M^2R_c}{R_g}\right]R_gI_{g(n)}=0 \tag{6}$$

Equation II. If Q_n and Q_{n+1} are the charges across the condenser during the nonconduction intervals of nth and $n+1$ half-cycles, then

$$Q_{n+1}=-Q_n+\frac{1}{\omega C}\int_{\pi-\alpha_n}^{\pi}i_{g(n)}d\omega t=-Q_n+\frac{\pi}{\omega C}I_{g(n)}$$

Since $Q_n=CV_n$, then

$$\frac{\pi}{\omega C}I_{g(n)}=V_n+V_{n+1}$$

This equation may be written as:

$$\pi\tan\bar{\phi}\left(1+\frac{M^2R_c}{R_g}\right)R_gI_{g(n)}=V_n+V_{n+1} \tag{7}$$

where

$$\bar{\phi}=\tan^{-1}\frac{1}{\omega C(R_g+M^2R_c)}$$

which is the effective phase angle during the conduction interval.

Equation III. During the nth conduction interval, reactor II is saturated while reactor I is unsaturated. The differential equation of the circuit is of the form:

$$[M^2R_c+R_g]i_{g(n)}+\frac{1}{C}\int i_{g(n)}dt=E^*+ME_c$$

Solution of this equation gives:

$$i_{g(n)}=K\epsilon^{-\frac{t}{R_g+M^2R_g}\frac{1}{C}}=K\epsilon^{-\tan\bar{\phi}\omega t}$$

Substituting the boundary condition

$$i_{g(n)}=\frac{E^*+V_n+ME_c}{(R_g+M^2R_c)}\text{ at }\omega t=\pi-\alpha_n$$

the value of the constant K may be determined. The equation of the current then becomes:

$$i_{g(n)}=\frac{E^*+V_n+ME_c}{(R_g+M^2R_c)}\epsilon^{\tan\bar{\phi}(\pi-\alpha_n)}\epsilon^{-\tan\bar{\phi}\omega t}$$

The half-cycle average value $I_{g(n)}$ of the current may be obtained by integrating this equation between the limits $\omega t=\pi-\alpha_n$ and $\omega t=\pi$ which gives:

$$[1-\epsilon^{-\tan\bar{\phi}\alpha_n}]=\frac{\pi\tan\bar{\phi}}{E^*+V_n+ME_c}\times\left[1+\frac{M^2R_c}{R_g}\right]R_gI_{g(n)} \tag{8}$$

From these three equations both the steady state and the transient behavior of the circuit may be obtained.

Steady-State Behavior

For steady-state operations equations 6, 7, and 8 reduce to

$$-2ME_c+2M^2R_cI_g=0 \tag{9}$$

$$\pi\tan\bar{\phi}\left(1+\frac{M^2R_c}{R_g}\right)R_gI_g=2V \tag{10}$$

$$[1-\epsilon^{-\tan\bar{\phi}\gamma}]=\frac{\pi\tan\bar{\phi}}{E^*+V+ME_c}\left[1+\frac{M^2R_c}{R_g}\right]R_gI_g \tag{11}$$

The first equation may be written as:

$$I_g=\frac{R_c}{MR_c}=\frac{I_c}{M} \tag{12}$$

This equation expresses analytically the fact that the circuit obeys the d-c transformer rule where the half-cycle average value of gate current equals the direct current flowing in the control winding, referred to the gate.

To determine the steady-state relationship between conduction angle and control voltage, equation 11 may be written

$$\epsilon^{-\gamma\tan\bar{\phi}}=\frac{E^*+V+ME_c-\pi\tan\bar{\phi}\left[\frac{M^2R_c}{R_g}+1\right]R_gI_g}{E^*+V+ME_c}$$

Elimination of V from this equation and equation 10 gives:

$$\epsilon^{-\gamma\tan\bar{\phi}}=\frac{E^*-\left[\frac{\pi\tan\bar{\phi}}{2}\left(\frac{M^2R_c}{R_g}+1\right)R_gI_g-ME_c\right]}{E^*+\left[\frac{\pi\tan\bar{\phi}}{2}\left(\frac{M^2R_c}{R_g}+1\right)R_gI_g+ME_c\right]}$$

Substituting the value of I_g given by equation 12 in this equation gives:

$$\epsilon^{-\gamma\tan\phi}=\frac{1-\left[\frac{\pi\tan\bar{\phi}}{2}\left(1+\frac{R_g}{M^2R_c}\right)-1\right]\frac{ME_c}{E^*}}{1+\left[\frac{\pi\tan\bar{\phi}}{2}\left(1+\frac{R_g}{M^2R_c}\right)+1\right]\frac{ME_c}{E^*}}$$

from which

$$\frac{ME_c}{E^*}=\frac{1}{\frac{\pi\tan\bar{\phi}}{2}\left[1+\frac{R_g}{M^2R_c}\right]\left[\frac{\epsilon^{\gamma\tan\bar{\phi}}+1}{\epsilon^{\gamma\tan\bar{\phi}}-1}\right]-1} \tag{13}$$

From this equation the steady-state nondimensional relationship between conduction angle and the control voltage may be calculated.

The steady-state behavior is not always possible since at some ranges of circuit parameters a low-frequency oscillation may occur where the half-cycle average value of current is no longer constant, but modulated by a low-frequency signal as shown in Fig. 6. This behavior may be predicted from the dynamic equations of the circuit as in the following section.

Oscillatory Behavior

Equation 8 contains nonlinear terms. The difficulty of solving this equation may be eliminated by making some justifiable approximations. For small variations about a given operating point, equation 8 may be written as:

$$1-\frac{\epsilon^{\tan\bar{\phi}(\gamma-\alpha_n)}}{\epsilon^{\tan\bar{\phi}\gamma}}=\frac{\pi\tan\bar{\phi}}{ME_c+E^*+V_n}\left[1+\frac{M^2R_c}{R_g}\right]R_gI_{g(n)}$$

where γ is a steady-state operation conduction angle about which a low-frequency oscillation α_n takes place. Thus, for small oscillation corresponding to small values $(\gamma-\alpha_n)$, this equation may be written as:

$$1-\frac{1+\gamma\tan\bar{\phi}-\tan\bar{\phi}\alpha_n}{\epsilon^{\tan\bar{\phi}\gamma}}=\frac{\pi\tan\bar{\phi}}{ME_c+E^*+V_n}\left[1+\frac{M^2R_c}{R_g}\right]R_gI_{g(n)}$$

This equation may be written as:

$$\alpha_n=\left[\frac{R_gI_{g(n)}}{ME_c+E^*+V_n}\right]K_1-K_2 \tag{14}$$

where K_1 and K_2 are constants corresponding to the steady-state conduction angle, and are given by:

$$K_1=\pi\epsilon^{\gamma\tan\bar{\phi}}\left[1+\frac{M^2R_c}{R_g}\right]$$

$$K_2=\frac{\epsilon^{\gamma\tan\bar{\phi}}-\gamma\tan\bar{\phi}-1}{\tan\bar{\phi}} \tag{15}$$

Substituting equation 14 in equation 6 gives:

$$[V_n - V_{n+1} - 2ME_c] - \frac{1}{\pi}[V_n + E^* + ME_c] \times \left[K_1\left(\frac{R_g I_{g(n)}}{ME_c + E^* + V_n}\right) - K_2\right] + \frac{1}{\pi}[V_{n+1} + E^* + ME_c] \times \left[K_1\left(\frac{R_g I_{g(n+1)}}{ME_c + E^* + V_n} + 1\right) - K_2\right] + \frac{2M^2R_c}{R_g} R_g I_{g(n)} = 0$$

from which

$$[V_n - V_{n+1} - 2ME_c] + \frac{K_2}{\pi}[V_n - V_{n+1}] - \frac{K_1}{\pi}[R_g I_{g(n)} - R_g I_{g(n+1)}] + \frac{2M^2R_c}{R_g} R_g I_{g(n)} = 0$$

This equation may be written as:

$$ME_c - \frac{M^2R_c}{R_g} R_g I_{g(n)} + \frac{K_1}{2\pi}[R_g I_{g(n)} - R_g I_{g(n+1)}] - \frac{1}{2}\left[1 + \frac{K_2}{\pi}\right][V_n - V_{n+1}] = 0 \quad (16)$$

The next step is to eliminate the V terms from this equation. This may be done as follows.

Letting $n = n+1$ and $n+1 = n+2$ in equation 16 gives:

$$ME_c - \frac{M^2R_c}{R_g} R_g I_{g(n+1)} + \frac{K_1}{2\pi}[R_g I_{g(n+1)} - R_g I_{g(n+2)}] - \frac{1}{2}\left[1 + \frac{K_2}{\pi}\right] \quad [V_{n+1} - V_{n+2}] = 0 \quad (17)$$

Adding equations 16 and 17 gives:

$$2ME_c - \frac{M^2R_c}{R_g} R_g I_{g(n)} + R_g I_{g(n+1)}] + \frac{K_1}{2\pi}[R_g I_{g(n)} - R_g I_{g(n+2)}] - \frac{1}{2}\left[1 + \frac{K_2}{\pi}\left[[(V_n + V_{n+1}) - (V_{n+1} + V_{n+2})] = 0 \quad (18)\right.\right.$$

Equation 7 may be written as:

$$V_n + V_{n+1} = \pi \tan \bar{\phi}\left(1 + \frac{M^2R_c}{R_g}\right) R_g I_{g(n)} \quad (19)$$

$$V_{n+1} + V_{n+2} = \pi \tan \bar{\phi}\left(1 + \frac{M^2R_c}{R_g}\right) R_g I_{g(n+1)} \quad (20)$$

Thus, substituting equations 19 and 20 in equation 18 gives:

$$R_g I_{g(n+2)} + \frac{\pi}{K_1}\left[\frac{2M^2R_c}{R_g} - \left(1 + \frac{K_2}{\pi}\right) \times \left(1 + \frac{M^2R_c}{R_g}\right)\pi \tan \bar{\phi}\right] R_g I_{g(n+1)} + \frac{\pi}{K_1}\left[\frac{2M^2R_c}{R_g} - \frac{K_1}{\pi} + \left(1 + \frac{K_2}{\pi}\right) \times \left(1 + \frac{M^2R_c}{R_g}\right)\pi \tan \bar{\phi}\right] R_g I_{g(n)} - \frac{4\pi}{K_1} ME_c = 0 \quad (21)$$

Letting

$$I_{g(n+1)} = I_{g(n)} + \Delta I_{g(n)}$$

and

$$I_{g(n+2)} = I_{g(n)} + 2\Delta I_{g(n)} + \Delta^2 I_{g(n)}$$

and arranging similar terms gives:

$$\Delta^2 I_{g(n)} + \left[2 + \frac{\pi}{K_1}\left\{\frac{2M^2R_c}{R_g} - \left(1 + \frac{K_2}{\pi}\right) \times \left(1 + \frac{M^2R_c}{R_g}\right)\pi \tan \bar{\phi}\right\}\right] \Delta I_{g(n)} + \left[\frac{4\pi}{K_1} \frac{M^2R_c}{R_g}\right] I_{g(n)} + \frac{4\pi}{K_1} \frac{ME_c}{R_g} = 0$$

Substituting values of K_1 and K_2 given by equation 15 in this equation gives:

$$\Delta^2 I_{g(n)} + \left[\epsilon^{+\gamma \tan \bar{\phi}} + \gamma \tan \bar{\phi} - \pi \tan \bar{\phi} + 1 + \frac{2}{1 + \frac{R_g}{M^2R_c}}\right] \epsilon^{-\gamma \tan \phi} \Delta I_{g(n)} + \frac{4\epsilon^{-\gamma \tan \phi}}{1 + \frac{R_g}{M^2R_c}}\left[I_{g(n)} - \frac{ME_c}{M^2R_c}\right] = 0$$

Letting $(I_{g(n)} - E_c/MR_c) = I_g{}'_{(n)}$, where $I_g{}'_{(n)}$ is the variation of the half-cycle average value of gate current from its steady-state average value, gives:

$$\Delta^2 I_{g(n)}{}' + B\Delta I_{g(n)}{}' + CI_{g(n)}{}' = 0 \quad (22)$$

where

$$B = \left[\epsilon^{+\gamma \tan \phi} + \gamma \tan \phi - \pi \tan \bar{\phi} + 1 + \frac{2}{1 + \frac{R_g}{M^2R_c}}\right] \epsilon^{-\gamma \tan \phi} \quad (23)$$

$$C = \left[\frac{4\epsilon^{-\gamma \tan \phi}}{1 + \frac{R_g}{M^2R_c}}\right] \quad (24)$$

This is the dynamic equation of the circuit, which is a second-order linear difference equation. For slow variations this difference equation may be approximated by a second-order differential equation of the form:

$$\frac{d^2 I_{g(n)}{}'}{dn^2} + B \frac{dI_{g(n)}{}'}{dn} + CI_{g(n)}{}' = 0 \quad (25)$$

This approximate equation is only valid for slow variations where both the critical condition for sustained oscillation and the frequency of oscillation may be calculated approximately. For more accuracy and faster variations the difference equation must be solved directly.

CRITICAL CONDITION FOR THE EXISTENCE OF LOW-FREQUENCY SUSTAINED OSCILLATION

At high values of control voltage, the circuit of Fig. 1 is stable. As the control is reduced, a critical point is reached where the circuit becomes unstable and oscillatory. The critical condition for sustained oscillation may be obtained from consideration of the stability of equation 22. For this equation to be stable three conditions must be satisfied:

1. $C > 0$
2. $2B - C < 4$
3. $B - C > 0$

From equation 24 it may be seen that C is always positive; that is, the first condition is always satisfied. From an examination of of equations 23 and 24 it may be seen that the second condition is always satisfied. Therefore, the reason for instability is the failure of the third condition. At the critical boundary between stable and unstable regions, $B = C$. Equating values of B and C given by equations 23 and 24 and letting $\gamma = \gamma_c$, gives:

$$\epsilon^{\gamma_c \tan \phi} + \gamma_c \tan \bar{\phi} - \pi \tan \bar{\phi} - \frac{2}{1 + \frac{R_g}{M^2R_c}} + 1 = 0 \quad (26)$$

From this equation the critical value of conduction angle γ_c at which the circuit becomes unstable may be determined. For values of γ below this critical value, the circuit is unstable.

The instability may or may not be associated with oscillatory behavior. The condition for sustained oscillation may be determined by taking the Laplace transform of equation 22, which gives:

$$[I_g{}'(S) - I_{g(0)}{}' - \epsilon^{-S} I_{g(1)}{}']\epsilon^{2S} + [B - 2] \times [I_g{}'(S) - I_{g(0)}{}']\epsilon^{S} + [1 - B + C] I_g{}'(S) = 0$$

Letting $\epsilon^S = Z$, this equation may be written as:

$$I_g{}'(Z) = \frac{[Z^2 + (B-2)Z] I_{g(0)}{}' + Z I_{g(1)}{}'}{Z^2 + [B-2]Z + [1 - B + C]}$$

The behavior of the circuit is oscillatory

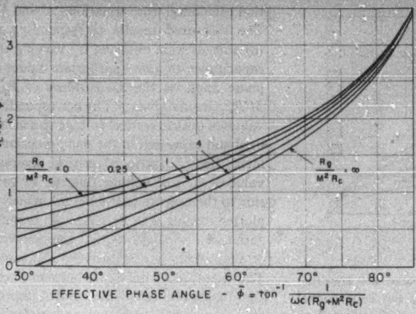

Fig. 7. Plot of $\gamma_c \tan \bar{\phi}$ against $\bar{\phi}$ calculated from equation 27 for series-connected saturable reactor with capacitive loading and finite control resistance for case of rectangular gate excitation and d-c control

when $B^2/4-C<0$. For this case this equation may be written as:

$$I_g'(Z)=\frac{[Z^2+(B-2)Z]I_{g(0)}'+ZI_{g(1)}'}{\left\{Z-\left[\left(1-\frac{B}{4}\right)+j\sqrt{C-\frac{B^2}{4}}\right]\right\}\times\left\{Z-\left[\left(1-\frac{B}{2}\right)-j\sqrt{C-\frac{B^2}{4}}\right]\right\}}$$

Assuming zero initial condition, $I_{g(0)}'=0$, this equation reduces to

$$I_g(Z)=\frac{ZI_{g(1)}'}{\left\{Z-\left[\left(1-\frac{B}{2}\right)+j\sqrt{C-\frac{B^2}{4}}\right]\right\}\times\left\{Z-\left[\left(1-\frac{B}{2}\right)-j\sqrt{C-\frac{B^2}{4}}\right]\right\}}$$

Frequency of Oscillation

Taking the inverse transform of equation 27 gives:

$$I_{g(n)}'=\frac{I_{g(1)}'}{2j\sqrt{C-\frac{B^2}{4}}}\times\left\{\left[\left(1-\frac{B}{2}\right)+j\sqrt{C-\frac{B^2}{4}}\right]^n-\left[\left(1-\frac{B}{2}\right)-j\sqrt{C-\frac{B^2}{4}}\right]^n\right\} \quad (27)$$

This equation may be put into the following form:

$$I_{g(n)}'=\frac{[1-B+C]^{n/2}}{\sqrt{C-\frac{B^2}{4}}}\,I_{g(1)}'\times\sin\left\{\left[\tan^{-1}\frac{\sqrt{C-\frac{B^2}{4}}}{\left(1-\frac{B}{2}\right)}\right]n\right\} \quad (28)$$

From this equation the frequency of oscillation referred to the duration of half a cycle taken as unit-time may be calculated and is given by

$$\frac{1}{2\pi}\tan^{-1}\left[\sqrt{C-\frac{B^2}{4}}\Big/\left(1-\frac{B}{2}\right)\right]$$

The true frequency of oscillation f_m may be obtained by dividing this frequency by $(1/2f)$ which is the time required for half a cycle. Thus

$$\frac{f_m}{f}=\frac{1}{\pi}\tan^{-1}\left[\sqrt{C-\frac{B^2}{4}}\Big/\left(1-\frac{B}{2}\right)\right] \quad (29)$$

From this equation the ratio of modulation to carrier frequency, (f_m/f), may be calculated, where B and C are given by equations 23 and 24.

At the critical point where the system just becomes unstable, $B=C$, thus equation 29 becomes

$$\frac{f_m}{f}=\frac{1}{\pi}\tan^{-1}\left[\sqrt{C-\frac{C^2}{4}}\Big/\left(1-\frac{C}{2}\right)\right]$$

Substituting the value of C given by equation 24 in this equation and letting $\gamma=\gamma_c$, gives:

$$\frac{f_m}{f}=\frac{1}{\pi}\tan^{-1}\left[\frac{\sqrt{\left(1+\frac{R_g}{M^2R_c}\right)\epsilon^{+\gamma_c\tan\bar{\phi}}-1}}{\frac{1}{2}\left(1+\frac{R_g}{M^2R_c}\right)\epsilon^{+\gamma_c\tan\bar{\phi}}-1}\right] \quad (30)$$

This equation gives the ratio of modulation to carrier frequency at the critical point where the circuit becomes oscillatory. The variation of (f_m/f) is smooth, that is, the low frequency oscillation is not necessarily a subharmonic frequency of the carrier.

Discussion of the Theoretical Results

The critical value of conduction angle γ_c at which the circuit becomes oscillatory is given by equation 26. This equation is represented graphically in Fig. 7, which is a plot of $(\gamma_c \tan \bar{\phi})$ against $\bar{\phi}$ for different values of $(R_g/M^2R_c)=0$, 0.25, 1, 4, and ∞, taken as parameters.

Substituting values of γ_c and the corresponding values of $\bar{\phi}$ expressed by the graphical relationship of Fig. 7 in equation 13, the critical value of control voltage corresponding to any value of phase angle may be calculated. This relationship is expressed graphically in Fig. 8, which is a plot of (ME_c/E^*) against $\bar{\phi}$, for different values of $(R_g/M^2R_c)=0$, 0.25, 1, 4, and ∞, taken as parameters.

Similarly substituting values of γ_c and the corresponding values of $\bar{\phi}$ expressed by the graphical relationship of Fig. 7 in equation 30, the ratio of modulation to carrier frequency (f_m/f) may be calculated. This relationship is expressed graphically in Fig. 9 which is a plot of (f_m/f) against

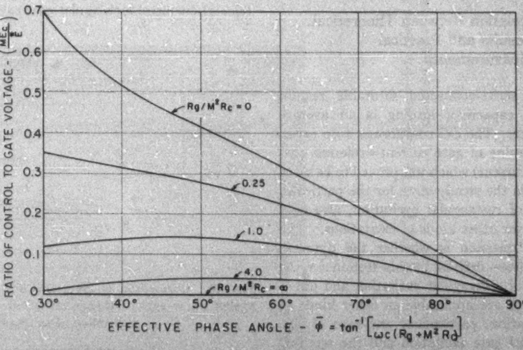

Fig. 8. Plot of ME_c/E^* (ratio of referred control voltage to gate voltage) against $\bar{\phi}$ (effective phase angle), calculated from equations 27 and 13 for series-connected saturable reactor with capacitive loading and finite control resistance for case of rectangular gate excitation and d-c control

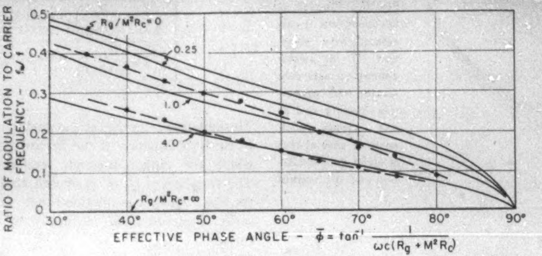

Fig. 9. Plot of f/f_m (ratio of modulation to carrier frequency) against $\bar{\phi}$ calculated from equations 27 and 30 for series-connected saturable reactor with capacitive loading and finite control resistance having rectangular gate excitation and d-c control. Two practical curves indicated on same figures were obtained from tabulated results of Fig. 11

$\bar{\phi}$ for fixed values of $(R_g/M^2R_c) = 0, 0.25, 1, 4$, and ∞ taken as parameters.

From these graphical relationships, the critical value of control voltage below which self-sustained oscillation starts and the frequency of these oscillations may be calculated. It may also be concluded that:

The modulation frequency is always less than the carrier frequency.

For a given value of R_g/M^2R_c, the modulation frequency decreases as the phase angle is increased.

For a given value of phase angle the modulation frequency decreases as R_g/M^2R_c is increased.

For a given value of R_g/M^2R_c the critical value of control voltage increases with the phase angle until it reaches a maximum; it then reduces gradually to zero as the phase angle is further increased.

For a given value of phase angle the critical value of control voltage decreases as R_g/M^2R_c is increased.

Correlation Between Theoretical Results and Practical Measurements

A series-connected saturable reactor with capacitive loading is an average device. The *CC* transformer rule (average value of gate current = referred control current) which was proved to be satisfied in the steady state for the particular case of rectangular excitation, also hold true for other kinds of excitations. The next question is whether the dynamic equations derived in this section for the case of rectangular excitation and direct control are applicable to other kinds of excitation, particularly the case of sinusoidal gate excitation and the rectified sinusoidal control. The answer to this question is that the dynamic behavior of the circuit changes with the condition of excitation; however, the behavior remains qualitatively the same, regardless of the waveshape of the forcing functions. The quantitative difference in the behavior in some ranges of operation is small enough that the dynamic behavior of the circuit is approximately the same regardless of the type of excitation. These conclusions were arrived at from the following investigations of the experimental series-connected saturable reactor circuit using two reactors of Fig. 4.

1. For three fixed values of $R_g/M^2R_c = 4$, 1, and 0.25, values of the critical control voltage corresponding to different values of effective phase angle $\bar{\phi} = \tan^{-1} 1/\omega C(R_g + M^2R_c)$, are plotted in Fig. 10 for these three cases:

(*a*). Rectified a-c control and sinusoidal gate excitation obtained by measurement on the experimental circuit.

(*b*). D-c control and sinusoidal gate excitation obtained by measurement on the experimental circuit.

(*c*). D-c control rectangular gate excitation calculated from equations 26 and 13.

The measured results corresponding to (*a*) and (*b*) were obtained by varying the capacitance to give appropriate values of phase angle at the fixed values of R_g/M^2R_c, already given. The corresponding values of critical control voltage was measured and expressed in the nondimensional form ME_c/E (ratio of critical average value of control voltage referred to gate side to the average gate voltage), which is plotted against $\bar{\phi}$ in Fig. 10. An investigation of Fig. 10 shows that the behavior of the circuit is qualitatively the same. The quantitative difference between these three cases reduces as the control impedance is reduced, such that at a value of $R_g/M^2R_c = 4$, the two measured curves for the case of sinusoidal excitation almost coincide and become closer to the theoretical results obtained by assuming a rectangular excitation.

2. For two fixed values of $R_g/M^2R_c = 4$, and 1, the waveshape of the gate current corresponding to different values of phase angle is given in the oscillograms of Figs. 11(A) and (B), respectively, for the case of sinusoidal gate excitation and d-c control. For each of these oscillograms corresponding to a fixed phase angle $\bar{\phi}$, the control current was adjusted to a critical value at which sinusoidal oscillation started, and the ratio of modulation to carrier frequency f_m/f was obtained by measurements on the oscillogram. Measured values of f_m/f together with the corresponding critical values of control current for different values of phase angle are tabulated in Fig. 11 and are plotted graphically in Fig. 9. From a comparison of these measured results with the theoretical curve of Fig. 9, it may be concluded that the theoretical analysis for the simplified

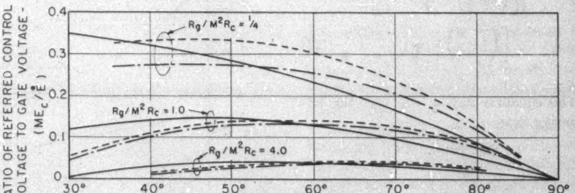

Fig. 10. Comparison of theoretical and measured values of critical control voltage plotted against phase angle. Theoretical results calculated from equations 27 and 13, deduced on assumption of rectangular gate excitation and d-c control

case of the practical circuit for the case of sinusoidal excitation, especially at low values of control resistance where the accuracy of prediction increases. The discrepancy between the measured and the theoretical curves is partly due to the magnetization current. The error due to the magnetization current increases as the phase angle is increased. This reasoning may be used to explain the discrepancy between theoretical and measured results at higher values of phase angle.

The circuit is very sensitive to changes in voltage at the critical point. At this point the circuit suddenly begins oscillating. Thus the critical control voltage may be easily measured. The amplitude, of oscillation increases appreciably with a slight reduction in control current. In the oscillograms of Fig. 11 for the gate current, the corresponding values of control voltage were kept larger or equal to the value where the modulation envelope just touches zero axis. For this case the oscillation is regular and may be predicted from the theoretical analysis. If the control voltage is reduced below the value where the modulation envelope touches the zero axis, the oscillation may become irregular and unpredictable. Such an irregular mode of oscillation may be seen from the oscillograms of Fig. 12, for the gate current flowing in the experimental circuit for the case of sinusoidal gate voltage and d-c control.

Conclusions

Magnetic amplifiers with capacitive loading may exhibit multivalued transfer characteristics containing jump phenomena. The solution of transcendental equations yield these steady-state transfer characteristics. In addition, in certain critical regions these circuits may become unstable and oscillate at a frequency less than the carrier frequency. This low-frequency oscillation acts to modulate the carrier frequency output. The use of difference equations and Z-transform techniques allows the prediction of the critical boundaries of the region in which these oscillations occur, and also the frequency of the oscillations.

Appendix. Nomenclature

A = effective core area, measured area × stacking factor of the core material
B_c = critical value of flux density at which the core saturates
C = load capacitance, farads
E = rms value of sinusoidal voltage applied to the gate of the series-connected saturable reactor
E_c = amplitude of the d-c control voltage of a series-connected saturable reactor
E_e = critical rms value of sinusoidal applied voltage at which extinction in a series-connected saturable reactor with capacitive loading takes place when control circuit is open
E_t' = critical transition voltage defined in reference 1 as the maximum rms value of a sinusoidal gate voltage applied to a series-connected saturable reactor with capacitive loading and infinite control impedance at which the appearance of mode IV is eliminated
E^* = amplitude of a rectangular alternating voltage applied to the gate of the series-connected saturable reactor
e = instantaneous value of voltage applied to the gate of the series-connected saturable reactor
e_I = instantaneous value of voltage across reactor I of the series-connected saturable reactor of Fig. 1
e_{II} = instantaneous value of voltage across reactor II of the series-connected saturable reactor of Fig. 2(A)
f = frequency of the gate (carrier) voltage applied to the series-connected saturable reactor
f_m = frequency of the envelope which modulates the average value of the gate current flowing in the series-connected saturable reactor of Fig. 6
I_c = value of direct current flowing in the control winding of the series-connected saturable reactor
$\bar{I}_c$ = value of direct current flowing in the control winding of the series-connected saturable reactor referred to the gate winding
I_g = half-cycle average value of current flowing in the gate winding of the series-connected saturable reactor
$I_{g(n)}, I_{g(n+1)}, I_{g(n+2)}$ = half-cyclic average value of the current flowing in the gate winding of the series-connected saturable reactor during n, $n+1$, $n+2$ half-cycle of the applied voltage
I_g' = variation of the half-cyclic-average value of the current flowing in the gate winding of the series connected-saturable reactor, from the mean average value
$I_g'_{(n)}, I_g'_{(n+1)}, I_g'_{(n+2)}$ = variation of the half-cyclic-average value of the current flowing in the gate winding of the series-connected saturable reactor during n, $n+1$, and $n+2$ half-cycle of the applied voltage, from the mean average value
i_c = instantaneous value of the current flowing in the control winding of the series-connected saturable reactor
i_g = instantaneous value of gate current flowing in the gate winding of the series-connected saturable reactor
$i_{g(n)}, i_{g(n+1)}, i_{g(n+2)}$ = instantaneous value of the gate current flowing in the gate winding of a series-connected saturable reactor during n, $n+1$, and $n+2$ half-cycles of the applied voltage
M = ratio of gate-to-control winding of the series-connected saturable reactor (N_g/N_c)
N_c = number of turns-per-control winding of the series-connected saturable reactor
N_g = number of turns-per-gate winding of the series-connected saturable reactor
Q = constant condenser charge during non-conduction intervals

Q_n, Q_{n+1}, Q_{n+2} = constant charge across the condenser during the nonconduction intervals of n, $n+1$, and $n+2$ half-cycle of the applied voltage
q = instantaneous value of condenser charge
q_n, q_{n+1}, q_{n+2} = instantaneous value of condenser charge during n, $n+1$, and $n+2$ half-cycle of the applied voltage
R_c = effective control resistance of the series-connected saturable reactor, $R_c = 2R_{wc}+R_{Lc}$
R_g = effective gate resistance of the series-connected saturable reactor, $R_g = 2R_{wg}+R_{Lg}$
R_{wc} = resistance of the control winding of the series-connected saturable reactor
R_{wg} = resistance of the gate winding of the series-connected saturable reactor
V = constant condenser voltage during nonconduction intervals
V_n, V_{n+1}, V_{n+2} = constant voltage across the condenser during the nonconduction intervals of n, $n+1$, and $n+2$ half-cycle of the applied voltage
v = instantaneous condenser voltage
β = instantaneous value of flux density
γ = steady-state operation, or mean conduction angle, during half a cycle of the a-c rectangular voltage applied to the gate winding of the series-connected saturable reactor with finite control resistance, during which current flows, and about which transient variation, or oscillation is assumed to take place
γ_c = critical value of the steady-state operation conduction angle below which the series-connected saturable reactor with capacitive loading and finite control impedance becomes unstable and oscillatory
Φ = total flux
$\bar{\phi}$ = effective phase angle of the series-connected saturable reactor of Fig. 1, $\bar{\phi} = \tan^{-1} 1/\omega C(R_g+M^2R_c)$, degrees or radians
ω = angular frequency of the gate (carrier) voltage applied to the series-connected saturable reactor
ω_m = angular frequency of the envelope which modulates the average value of the gate current flowing in the series-connected saturable reactor, Fig. 6.

Analysis of Magnetic Amplifiers Without Diodes

PAUL R. JOHANNESSEN
ASSOCIATE MEMBER AIEE

ALTHOUGH THERE ARE many methods and procedures for analyzing complex circuits, probably the best-known general approach is to apply an organized, systematic procedure to the combination of the analytic expressions for the voltage-current characteristics of the individual circuit elements. To be able to apply this method of attack, it is essential that the characteristics of the individual circuit elements, if such elements can be defined, can be represented by analytic expressions, and that an organized method exists where the analytic representations of the individual circuit elements can be combined to yield the desired result.

In this paper the foundation for such an analysis will be established for magnetic amplifiers without diodes. The element to be considered as the basic magnetic-amplifier element consists of a 2-winding saturable inductor, one winding being in series with an alternating voltage source. Both the saturable inductor and the alternating voltage source are fundamental to the magnetic amplifier, because either element without the other cannot provide power amplification.[1] By proper choice of variables and the use of certain assumptions regarding component characteristics and voltage waveforms, it will be shown that the analytic representation of the basic magnetic-amplifier element can be made linear.

Analysis of Basic Magnetic-Amplifier Element

The basic magnetic-amplifier element, shown in Fig. 1(A), consists of a saturable inductor and an alternating-voltage source. There are two windings on the inductor: the gate winding in series with the source and port 2; and the control winding in series with port 1. In the analysis of the basic element, the inductor characteristics are considered to be ideal and the two inductor windings are assumed to be perfectly coupled. To simplify the analytic expressions obtained, a one-to-one turns ratio of the two windings is also assumed. A different turns ratio can easily be taken into account by the use of an ideal transformer. Because of the assumptions of ideal coupling and one-to-one turns ratio, the inductor can be considered as a 1-winding inductor that is either a short circuit or a open circuit, depending upon the flux level in the inductor core. In fact, the two windings are introduced merely to make possible the interconnections of basic elements to be considered later; at present, the inductor can be thought of to advantage as a 1-winding inductor.

The analysis assumes, initially, arbitrary waveforms for the supply and port voltages. In the course of the analysis the restrictions upon the waveforms that lead to a linear analysis will be established. At this stage the only restriction imposed upon the supply voltage is that its magnitude be limited so that the volt-time integrals of the positive and negative parts are less than the volt-time integral required to drive the core from positive to negative saturation. This requirement can be stated analytically as follows:

$$\int_{t_a}^{t_b} e_s dt < 2n_s AB_s \qquad (1)$$

where

e_s = source voltage
t_a = time of the beginning of a positive or negative half period of e_s

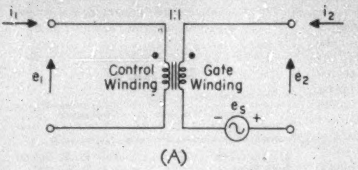
Paul R. Johannessen is with the Applied Research Laboratory of the Sylvania Electronics System, Waltham, Mass.

The material presented in this paper was submitted to the Massachusetts Institute of Technology, Cambridge, Mass. in partial fulfillment of the requirements for the Doctor of Science degree. It was supported by the U. S. Air Force under Contract No. *AF 33(616)-5489*, MIT Project No. *DSR 7848*.



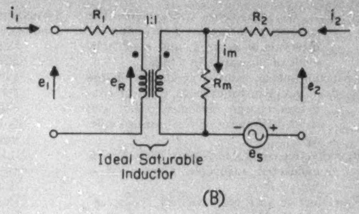


Fig. 1. A—Basic magnetic-amplifier element. B—The modified element

t_b = time of the ending of the same half period
n_2 = number of turns on the gate winding
A = cross section of the core
B_s = saturation flux density of the core

To avoid difficulties that are usually associated with the analysis when zero and infinite impedances or admittances occur, the resistors R_1, R_2, and R_m are added to the basic circuit as shown in Fig. 1(B). The resistors R_1 and R_2 will later be considered to represent the winding resistances, and the resistor R_m to represent the magnetizing impedance of the inductor. At present, however, these resistors are introduced only for convenience. The characteristics of the inductor in Fig. 1(B) are shown in Fig. 2. The scales of the plot are chosen in such a way that the usual B versus H curve is converted into an $\int e_R dt$ versus i_R curve e_R being the ideal saturable-inductor voltage and i_R the inductor current.

To simplify the analysis a fictitious voltage e_R' is introduced. The voltage e_R' is defined as the voltage that would appear across the inductor if the inductor were open-circuited, and it is given by the following expression:

$$e_R' = ae_1 + b(e_s + e_2) \tag{2}$$

where

a = voltage transfer ratio between the e_1 and the e_R terminals, measured with $e_2 = e_s = 0$
b = voltage transfer ratio between the e_s, or e_2, and the e_R terminals, measured with e_2 (or e_s) $= e_1 = 0$

In terms of the circuit parameters, expressions for a and b are as follows:

$$a = \frac{R_m R_2/(R_m + R_2)}{R_1 + R_m R_2/(R_m + R_2)} \tag{3}$$

$$b = \frac{R_m R_1/(R_m + R_1)}{R_2 + R_m R_1/(R_m + R_1)} = \frac{R_1}{R_2} a \tag{4}$$

During the unsaturated period e_R' is the voltage across the inductor. By Thevenin's theorem it is also seen that if R is the resistance faced by the inductor, e_R'/R is the current in the inductor during the saturated period. The component ae_1 of e_R', together with the *negative* of the component $b(e_s+e_2)$, is plotted in Fig. 3. For reference polarities as in Fig. 1(B), the inductor current e_R'/R must be positive during saturation on the upper branch of the inductor characteristic. Thus e_R' must be positive,

$$ae_1 > -b(e_s + e_2) \tag{5}$$

that is, saturation on the upper branch of the inductor characteristic can occur only when the voltage component ae_1 is above the voltage component $-b(e_s+e_2)$ in Fig. 3. Particular attention should be given to the intersections of the two voltage-component curves, because at these instants, labeled t_1, t_2, and t_1' in Fig. 3, both the inductor voltage and the inductor current are zero. If the inductor saturates on the upper branch of the characteristic, saturation must end at the intersections t_1 and t_1'. Similarly, if the inductor saturates on the lower branch of its characteristics, saturation must end at the intersection t_2.

Suppose that at time t_0 the inductor is saturated and that the operating point P on the inductor characteristic is at point P_0 in Fig. 2. Saturation continues and the inductor voltage e_R is zero until the intersection at time t_1 of the component voltages. During the time interval t_0 to t_1, the operating point P moves from P_0 to P_1. After t_1, the inductor is unsaturated; the inductor voltage e_R is equal to the fictitious voltage e_R' which is negative; and the operating point P moves from P_1 down to P_2 during the interval t_1 to t_2. After t_2, the inductor voltage is positive and the operating point P moves back up to P_1 in the interval t_2 to t_3. Because the flux change from P_1 to P_2 is equal to the negative of the flux change from P_2 to P_1, the integral of the inductor voltage during the intervals t_1 to t_2 and t_2 to t_3 must satisfy the equation

$$\int_{t_2}^{t_3} e_R dt = -\int_{t_1}^{t_2} e_R dt \tag{6}$$

or the two areas shaded in Fig. 3 must be equal. At t_3 the inductor saturates; the voltage e_R drops to zero; and saturation continues until t_1', a point in the next period of operation which corresponds to the point t_1 in the first period considered.

The important conclusions from the foregoing considerations are that during the saturated period the inductor voltage is zero and that during the unsaturated period the integral of the inductor voltage is zero; or

$$\int_{t_1}^{t_3} e_R dt = 0 \tag{7}$$

Therefore, during the entire period from

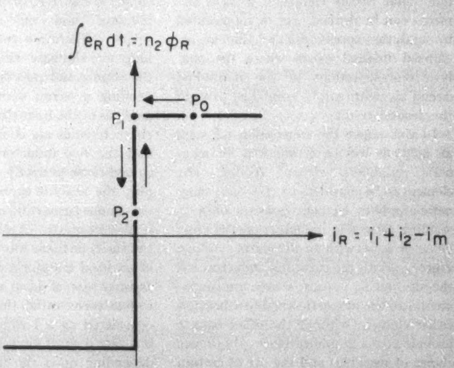

Fig. 2. Ideal saturable inductor

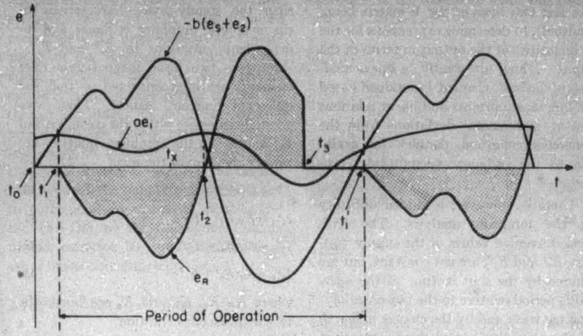

Fig. 3. Voltage waveforms

t_1 to t_1' called the operating period, the integral of the inductor voltage e_R is zero.

The only conditions of the voltage waveforms thus far are:

1. Saturation must occur periodically so that a succession of periods like t_1 to t_1' occur.
2. Saturation must occur at only one end of the inductor characteristic.

For convenience in the remainder of this analysis the following conditions are added:

3. The voltage waveforms must be such that exactly one saturated and one unsaturated period occur in each operating period.
4. The average value of the supply voltage over any complete supply-voltage period must be zero.

Consider now any instant of time t_x within the period t_1 to t_1'. Time t_x divides the operating period into two parts, t_1 to t_x and t_x to t_1'; the first of these periods is called the control period and the second the gating period.

The following relation can now be written

$$\int_{t_1}^{t_x} e_R dt+\int_{t_x}^{t_1'} e_R dt=0 \tag{8}$$

Therefore

$$\frac{t_x-t_1}{t_x-t_1}\int_{t_1}^{t_x} e_R dt+\frac{t_1'-t_x}{t_1'-t_x}\int_{t_x}^{t_1'} e_R dt=0 \tag{9}$$

or

$$(t_x-t_1)E_R^c+(t_1'-t_x)E_R^g=0 \tag{10}$$

where

E_R^c = average value of e_R in the control period

E_R^g = average value of e_R in the gating period

If time t_x divides the interval from t_1 to t_1' into two equal parts so that

$$t_x-t_1=t_1'-t_x \tag{11}$$

the basic relation of equation 10 simplifies to

$$E_R^c+E_R^g=0 \tag{12}$$

It should be realized that the choice of t_x is entirely arbitrary, and the center position is preferred merely because it simplifies the result of the analysis. It will be shown later that there are no compensating disadvantages to this choice for practical circuits. It is also of importance to realize that time t_x does not correspond to time t_3, the instant of time at which the inductor saturates. As a consequence, the control and gating periods do not correspond to the unsaturated and saturated periods. Furthermore, there is no special relation between t_x and t_3; that is, the interval of time during which e_R is negative can be more or less than half the t_1 to t_1' period.

If port 2 is short-circuited and zero signal is applied to port 1, equation 2 reduces to

$$e_R'=be_s \tag{13}$$

Since the voltage e_s by definition does not contain a direct voltage component, the inductor does not saturate; that is, in Fig. 3, t_3 coincides with t_1'. If a positive voltage is applied to port 1, t_3 moves back from t_1' toward t_1. Thus, with small signals applied, t_3 may be expected to occur after t_x, that is in the gating period; only with very large applied signals at port 1 can t_3 occur in the control period. The analysis of interest is concerned primarily with relatively small signals. Also, in practical magnetic amplifiers it is unusual and undesirable for the saturation period, t_3 to t_1', to extend into the control period. It is, therefore, here assumed that t_3 remains in the gating period. This assumption renders the basic circuit linear throughout the control period so that voltage-current relations can be calculated easily.

At any instant at all, the following equations hold

$$e_1=R_1i_1+e_R \tag{14}$$

$$e_2+e_s=R_2i_2+e_R \tag{15}$$

In addition, at any instant in the control period,

$$e_R=ae_1+b(e_s+e_2) \tag{16}$$

These equations completely determine the relations between port quantities during the control period so that any of the 2-port matrices may be calculated. For example, the equations may be solved to yield the admittance-matrix equation:

$$\left\|\begin{matrix} i_1 \\ i_2 \end{matrix}\right\| = \left\|\begin{matrix} \frac{1-a}{R_1} & \frac{-b}{R_1} & \frac{-b}{R_1} \\ \frac{-a}{R_2} & \frac{1-b}{R_2} & \frac{1-b}{R_2} \end{matrix}\right\| \left\|\begin{matrix} e_1 \\ e_2 \\ e_s \end{matrix}\right\| \tag{17}$$

Since these equations are true at each instant, they are also true for average values during the control period.

$$\left\|\begin{matrix} I_1^c \\ I_2^c \end{matrix}\right\| = \left\|\begin{matrix} \frac{1-a}{R_1} & \frac{-b}{R_1} & \frac{-b}{R_1} \\ \frac{-a}{R_2} & \frac{1-b}{R_2} & \frac{1-b}{R_2} \end{matrix}\right\| \left\|\begin{matrix} E_1^c \\ E_2^c \\ E_s^c \end{matrix}\right\| \tag{18}$$

Here, and in subsequent equations, the notation introduced in equation 10 is used; capital letters with superscript *c* are used to denote control-period average values of the quantity denoted by the corresponding lower-case letters. Superscript *g* is used to denote the gating-period average value.

Instantaneous-value equations for the gating period are more difficult to obtain, and a different approach, therefore, is used to derive average-value equations for this period. Equations 14 and 15 are valid at any instant, and in terms of average values in the gating period become

$$E_1^g=R_1I_1^g+E_R^g \tag{19}$$

$$E_2^g+E_s^g=R_2I_2^g+E_R^g \tag{20}$$

By the use of the basic relation

$$E_R^c+E_R^g=0 \tag{12}$$

together with equations 16, 18, 19, and 20, equations analogous to equation 18 can be obtained; and these with equation 18 may be written as the admittance-matrix equation of the network:

$$\left\Vert\begin{matrix} I_1^c \\ \\ I_1^g \\ \\ I_2^c \\ \\ I_2^g \end{matrix}\right\Vert = \left\Vert\begin{matrix} \frac{1-a}{R_1} & 0 & \frac{-b}{R_1} & 0 & \frac{-b}{R_1} & 0 \\ \\ \frac{a}{R_1} & \frac{1}{R_1} & \frac{b}{R_1} & 0 & \frac{b}{R_1} & 0 \\ \\ \frac{-a}{R_2} & 0 & \frac{1-b}{R_2} & 0 & \frac{1-b}{R_2} & 0 \\ \\ \frac{a}{R_2} & 0 & \frac{b}{R_2} & \frac{1}{R_2} & \frac{b}{R_2} & \frac{1}{R_2} \end{matrix}\right\Vert \left\Vert\begin{matrix} E_1^c \\ E_1^g \\ E_2^c \\ E_2^g \\ E_s^c \\ E_s^g \end{matrix}\right\Vert \tag{21}$$

More generally, any desired network matrix can be obtained from these same equations.

Equation 21 appears to indicate that in terms of half-period average values, the basic element can be represented as a linear network containing a source, E_s. Thus, if short circuits are placed at input and output, the following quiescent currents flow:

In the control period,

$${I_1^c}_q = -\frac{b}{R_1}\, E_s^c \tag{22}$$

$${I_2^c}_q = \frac{1-b}{R_2}\, E_s^c \tag{23}$$

In the gating period,

$${I_1^g}_q = \frac{b}{R_1}\, E_s^c \tag{24}$$

$${I_2^g}_q = \frac{b}{R_2}\, E_s^c + \frac{1}{R_2}\, E_s^g \tag{25}$$

As is shown by equations 22 through 25 only alternating currents flow during quiescent condition, inasmuch as E_s^c is equal to $-E_s^g$ in steady-state operation. This result is obvious because no direct-voltage sources are present in the circuit when both network ports are short-circuited.

If now a signal is applied at port 1 with 2 left short-circuited, additional components of currents flow as follows:

$$\Delta I_1^c = \frac{1-a}{R_1}\, E_1^c \tag{26}$$

$$\Delta I_2^c = -\frac{a}{R_2}\, E_1^c \tag{27}$$

$$\Delta I_1^g = \frac{a}{R_1}\, E_1^c + \frac{1}{R_1}\, E_1^c \tag{28}$$

$$\Delta I_2^c = \frac{a}{R_2}\, E_1^c \tag{29}$$

If port 2 is opened and a load applied, the characteristics of the load determine the voltage and current relations at port 2. If the load characteristics can be formulated as a linear relationship among E_2^c, E_2^g, I_2^c, and I_2^g, then the equations stating this relationship can be used with the matrix equation, equation 21 (the last two columns of the Y-matrix and the last two rows of the E-matrix being omitted), to determine expressions for the Δ quantities at the output in terms of the input. Thus, apparently, a linear analysis of the basic element is obtained based on quiescent currents and linear relations among incremental deviations from the quiescent condition, parallel, for example, to the ordinary vacuum-tube procedure.

There is, however, a hidden difficulty in the foregoing analysis. The half-period average values of the supply voltage, E_s^c and E_s^g, are not constant, but are altered by the shift in time of the operating period relative to the power supply-voltage wave and by the change in length of the operating period during transient conditions. This property is seen from Fig. 3, because both t_1 and t_1' are determined by the intersections of the two waves, $-b(e_s+e_2)$ and ae_1, representing components of the fictitious voltage e_R'. If both e_1 and e_2 are zero, t_1 and t_1' are located at the zero crossings of the e_s wave. Existence of the voltages e_1 and e_2 tends to shift t_1 and t_1' from these zero crossings. Thus, a nonlinearity in the basic element is hidden in the terms involving E_s^c and E_s^g and their dependency on the signal.

During steady-state conditions the period of operation t_1 to t_1' is equal to the period T of the power-supply voltage wave so that the nonlinearity in the basic element during steady-state conditions is caused by the shift in the period of operation relative to the power-supply voltage wave only. For practical magnetic amplifiers consisting of interconnections of basic elements, this nonlinearity is usually canceled. For this cancellation to occur, the terms involving E_s^c and E_s^g in the equations representing the operation of a practical magnetic amplifier must cancel one another. Fortunately, conditions under which the terms involving E_s^c and E_s^g cancel can be determined as follows. Equation 21 is a set of linear relations among the half-period average values of the supply voltage and port voltages and currents. It should be realized that in the derivation of these relations the restriction that the supply voltage should remain constant was not imposed. Superposition can therefore be used to determine the effect of variations in the quantities E_s^c and E_s^g upon the magnetic-amplifier operation. It is immaterial what causes the quantities E_s^c and E_s^g to vary. Thus, if it can be shown that the changes in E_s^c and E_s^g, caused by the shift in the period of operation relative to the period of the supply voltage wave, do not affect the quiescent operating conditions, then the steady-state characteristic of the magnetic amplifier is linear and independent variations in E_s^c and E_s^g.

Suppose two basic magnetic-amplifier elements are interconnected so that the quiescent current cancel. Then two possibilities exist; either the coefficients of E_s^c and E_s^g in the amplifier equations are zero or they are of the form

$${I_1^c}_q = K_1(E_s^c + E_s^g) \tag{30}$$

$${I_1^g}_q = K_2(E_s^c + E_s^g) \tag{31}$$

$${I_2^c}_q = K_3(E_s^c + E_s^g) \tag{32}$$

$${I_2^g}_q = K_4(E_s^c + E_s^g) \tag{33}$$

where K_1, K_2, K_3, and K_4 are constants. In the quiescent condition

$$E_s^c = -E_s^g \tag{34}$$

so that the desired quiescent-current cancellation is ensured. During steady-state operation the changes in E_s^c and E_s^g must satisfy the relation

$$\Delta E_s^c + \Delta E_s^g = 0 \tag{35}$$

because the supply voltage contains no direct voltage component and is periodic. Changes in E_s^c and E_s^g during steady-state operation, therefore, do not cause any changes in the short-circuit port currents. Thus, it follows that magnetic amplifiers whose quiescent currents are zero have linear steady-state characteristics independent of variations in E_s^c and E_s^g.

For a single basic element the error introduced by ignoring the variation of the E_s^c and E_s^g terms is not so great as might appear, as is demonstrated in reference 2.

Linear Analytic Representation of the Basic Element

A linear analytic representation of the basic element in terms of incremental half-period average quantities is obtained by eliminating the last two columns in the admittance matrix and the last two rows in the voltage matrix of equation 21, and adding a Δ to the current and voltage symbols. For convenience the added symbol Δ is omitted in writing the following equation.

$$\left\Vert\begin{matrix} I_1^c \\ \\ I_1^g \\ \\ I_2^c \\ \\ I_2^g \end{matrix}\right\Vert = \left\Vert\begin{matrix} \frac{1-a}{R_1} & 0 & \frac{-b}{R_1} & 0 \\ \\ \frac{a}{R_1} & \frac{1}{R_1} & \frac{b}{R_1} & 0 \\ \\ \frac{-a}{R_2} & 0 & \frac{1-b}{R_2} & 0 \\ \\ \frac{a}{R_2} & 0 & \frac{b}{R_2} & \frac{1}{R_2} \end{matrix}\right\Vert \left\Vert\begin{matrix} E_1^c \\ \\ E_1^g \\ \\ E_2^c \\ \\ E_2^g \end{matrix}\right\Vert \tag{36}$$

In the analysis of magnetic amplifiers

Vol.
Pt. 1
1959

not only the static but also the dynamic properties are of interest. The dynamic properties of the basic element are apparent from the superscript notation used, which indicates that the short-circuit currents in the gating period depend on the port voltages in both the control period and the gating period. Thus, a time-delay of one-half period exists, for example, between E_1^c and I_2^g. If the *n*th half cycle of the supply voltage is taken to correspond to a control period, and the $(n+1)th$ to the subsequent gating period, equation 36 can be written as a set of linear difference equations.

$$I_1^c(n)=\frac{1-a}{R_1}E_1^c(n)-\frac{b}{R_1}E_2^c(n)$$

$$I_1^g(n+1)=\frac{a}{R_1}E_1^c(n)+\frac{1}{R_1}E_1^g(n+1)+\frac{b}{R_1}E_2^c(n) \qquad (37)$$

$$I_2^c(n)=-\frac{a}{R_1}E_1^c(n)+\frac{1-b}{R_2}E_2^c(n)$$

$$I_2^g(n+1)=\frac{a}{R_2}E_1^c(n)+\frac{b}{R_2}E_2^c(n)+\frac{1}{R_2}E_2^g(n+1)$$

For the analytic representation of the basic element to serve as a means for analysis of magnetic amplifiers, a more convenient representation than offered by equation 37 is desirable. In linear-circuit analysis such a representation is usually obtained by a transformation from the time domain to the frequency domain, accomplished by either the Fourier or Laplace transform, because such a transformation reduces the mathematical manipulation to simple algebra. To apply this method, however, it is necessary that the variable quantities be transformable. Clearly, the Laplace transform of an average-value quantity has no meaning. Also, there exists no fixed relation between instantaneous voltages and currents of a magnetic amplifier, because the waveforms of the dependent variables depend not only upon the waveform of the independent variables but also upon the waveform of the supply voltage. On an instantaneous basis, therefore, the Laplace transform does not exist. However, for the purpose of analysis, any waveform can be assigned to the variable quantities in equation 37; and, to permit the use of the Laplace-transform method, it is assumed that the variable quantities consist of impulses whose areas are equal to the magnitude of the average-value quantities. This choice of wave form is by no means the only possible one, but is made for convenience. The Laplace transform of the difference equations can now be obtained and yields

$$\left\|\begin{matrix} I_1^c(s) \\ I_1^g(s) \\ I_2^c(s) \\ I_2^g(s) \end{matrix}\right\| = \left\|\begin{matrix} \frac{1-a}{R_1} & 0 & \frac{-b}{R_1} & 0 \\ \frac{a}{R_1}\cdot\frac{1}{z} & \frac{1}{R_1} & \frac{b}{R_1}\cdot\frac{1}{z} & 0 \\ \frac{-a}{R_2} & 0 & \frac{1-b}{R_2} & 0 \\ \frac{a}{R_2}\cdot\frac{1}{z} & 0 & \frac{b}{R_2}\cdot\frac{1}{z} & \frac{1}{R_2} \end{matrix}\right\| \left\|\begin{matrix} E_1^c(s) \\ E_2^c(s) \\ E_1^g(s) \\ E_2^g(s) \end{matrix}\right\| \qquad (38)$$

where

$$z=e^{\frac{T}{2}s} \qquad (39)$$

and where a bar over a symbol is used to denote the Laplace transform of the time function represented by the symbol itself.

The elements of the admittance matrix in equation 38 are the short-circuit driving point and transfer admittances of the basic magnetic-amplifier element. The admittance matrix and its elements may be written

$$Y=\left\|\begin{matrix} y_{11}^{cc} & y_{11}^{cg} & y_{12}^{cc} & y_{12}^{cg} \\ y_{11}^{gc} & y_{11}^{gg} & y_{12}^{gc} & y_{12}^{gg} \\ y_{21}^{cc} & y_{21}^{cg} & y_{22}^{cc} & y_{22}^{cg} \\ y_{21}^{gc} & y_{21}^{gg} & y_{22}^{gc} & y_{22}^{gg} \end{matrix}\right\| \qquad (40)$$

Because impulses are chosen as the waveform of the variable quantities, these admittances can be interpreted simply as the Laplace transform of the unit impulse response. For example, the inverse transform of the y_{21}^{gc} transfer admittance is the short-circuit current at port 2 during the gating periods caused by a voltage applied at port 1 during the first control period (the control period from time 0 to $T/2$).

The admittance matrix of equation 40 can be partitioned into four 2×2 submatrices by writing

$$Y_{rs}=\left\|\begin{matrix} y_{rs}^{cc} & y_{rs}^{cg} \\ y_{rs}^{gc} & y_{rs}^{gg} \end{matrix}\right\| \qquad (41)$$

where *r* and *s* may each be 1 or 2. Thus, the matrix of equation 40 can be written

$$Y=\left\|\begin{matrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{matrix}\right\| \qquad (42)$$

The reader should note that the matrix elements in equation 42 represent submatrices of the form shown by equation 41.

Other relations between port voltages and currents useful in magnetic-amplifier analysis are the following:

$$\left\|\begin{matrix} E_1^c \\ E_1^g \\ E_2^c \\ E_2^g \end{matrix}\right\| = Z \left\|\begin{matrix} I_1^c \\ I_1^g \\ I_2^c \\ I_2^g \end{matrix}\right\| \qquad (43)$$

$$\left\|\begin{matrix} E_1^c \\ E_1^g \\ I_2^c \\ I_2^g \end{matrix}\right\| = H \left\|\begin{matrix} I_1^c \\ I_1^g \\ E_2^c \\ E_2^g \end{matrix}\right\| \qquad (44)$$

$$\left\|\begin{matrix} I_1^c \\ I_1^g \\ E_2^c \\ E_2^g \end{matrix}\right\| = G \left\|\begin{matrix} E_1^c \\ E_1^g \\ I_2^c \\ I_2^g \end{matrix}\right\| \qquad (45)$$

and

$$\left\|\begin{matrix} E_1^c \\ E_1^g \\ I_1^c \\ I_1^g \end{matrix}\right\| = \left\|\begin{matrix} A & -B \\ C & -D \end{matrix}\right\| \left\|\begin{matrix} E_2^c \\ E_2^g \\ I_2^c \\ I_2^g \end{matrix}\right\| \qquad (46)$$

The analytic expressions for the matrix components of equations 43 through 46 can readily be obtained from equation 38 and are given in the Appendix.

The fundamental relations of the basic element have been derived in matrix form, this form being particularly useful in the analysis of magnetic amplifiers resulting from interconnections of basic elements. Two ordinary 2-port networks can be interconnected in five fundamental ways:

1. cascade
2. parallel
3. series
4. series-parallel
5. parallel-series

The analysis of these interconnections reduces to simple matrix addition or multiplication if the proper analytic representation for the individual networks is used.[8] The matrices *Y*, *Z*, *H*, *G*, and *ABCD* were all derived in order to have available the appropriate analytic representation for the various fundamental interconnections. It is pointed out that there is an important restriction to the matrix method, when interconnections *b*, *c*, *d*, and *e* are of interest. If a potential difference exists between the terminals to be joined in the interconnection of two networks, a circulating current will result and the combined behavior will not be given by superposition of the previous individual behaviors. For the basic amplifier under consideration, however, this restriction does not apply, since complete isolation exists between the two ports; and superposition of the behavior of the individual elements can always be used to determine the combined behavior. In the following section, the rules of interconnection of basic elements are developed.

Interconnection of Two Basic Elements

In the previous section it was stated that two 2-port networks can be interconnected in five fundamental ways.

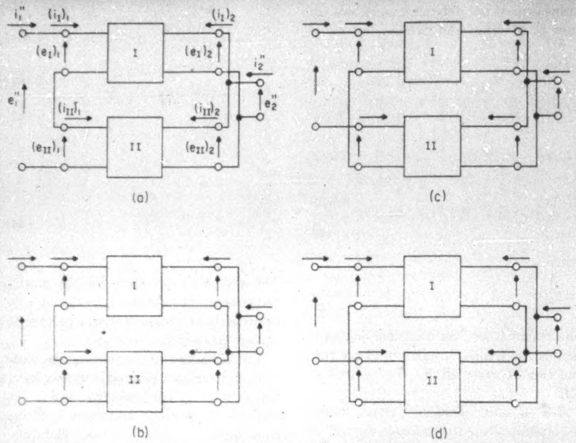

Fig. 4. The four possible subconnections for the series parallel interconnection of 2-port networks

Each of the fundamental interconnections, in turn, can be made in four possible ways, shown in Fig. 4 for the fundamental series-parallel interconnection. As demonstrated by Guillemin,[3] the analytic representation of the interconnected network can easily be obtained by choosing the proper matrix representations of the individual networks. The various subconnections of Fig. 4 can be taken into account by a simple transformation of the variables of one of the networks as will be shown next.

The proper analytic representation for the series-parallel interconnection is given by the H-matrix. Let H_I be the matrix of network I, and H_{II} be the matrix of network II when the port voltage and current polarities are as shown in Fig. 4. The following equations are then valid

For network I,

$$\begin{Vmatrix}(\bar{E}_I)_1\\(\bar{I}_I)_2\end{Vmatrix}=H_I\begin{Vmatrix}(\bar{I}_I)_1\\(\bar{E}_I)_2\end{Vmatrix} \tag{47}$$

For network II,

$$\begin{Vmatrix}(\bar{E}_{II})_1\\(\bar{I}_{II})_2\end{Vmatrix}=H_{II}\begin{Vmatrix}(\bar{I}_{II})_1\\(\bar{E}_{II})_2\end{Vmatrix} \tag{48}$$

where the subscript I refers to network I and the subscript II refers to network II. If the two networks under consideration represent ordinary linear networks, the variable quantities in equations 47 and 48 are the Laplace transform of the instantaneous port voltages and currents. If, however, the two networks represent basic magnetic-amplifier elements, then the varible quantities in equations 47 and 48 are 1×2 submatrices in which the elements are the Laplace transforms of half-period average voltages and currents as defined in the previous section.

The constraints imposed upon the port voltages and currents of the individual networks of the various subconnections are

$$(\bar{E}_I)_2=\pm(\bar{E}_{II})_2 \tag{49}$$

$$(\bar{I}_I)_1=\pm(\bar{I}_{II})_1 \tag{50}$$

where the four possible combinations of sign represent the four possible subconnections.

The port voltages and current of the combination network for the various subconnections can be written in terms of the port voltages and currents of the individual networks as follows:

$$\bar{E}_1''=(\bar{E}_I)_1\pm(\bar{E}_{II})_1 \tag{51}$$

$$\bar{I}_1''=(\bar{I}_I)_1 \tag{52}$$

$$\bar{E}_2''=(\bar{E}_I)_2 \tag{53}$$

$$\bar{I}_2''=(\bar{I}_I)\pm(\bar{I}_{II})_2 \tag{54}$$

where the double-primed variable quantities are the port voltages and currents of the combination network. Note that for a particular subconnection the last terms in equations 49 and 54 have the same sign and also that the last two terms in equations 50 and 51 have the same sign. The sign of the last terms in equations 49 and 54, however, might differ from the sign of the last terms in equations 50 and 51 depending upon the particular subconnection under consideration.

A new set of variables now will be introduced. Let

$$\bar{E}_1'=\pm(\bar{E}_{II})_1 \tag{55}$$

$$\bar{E}_2'=\pm(\bar{E}_{II})_2 \tag{56}$$

and

$$\bar{I}_1'=\pm(\bar{I}_{II})_1 \tag{57}$$

$$\bar{I}_2'=\pm(\bar{I}_{II})_2 \tag{58}$$

where again, for a particular subconnection, the terms in equations 55 and 57 have the same sign, and the terms in equations 56 and 58 have the same sign. Because of this property equations 55 through 58 can be written as follows:

$$\begin{Vmatrix}(\bar{E}_{II})_1\\(\bar{I}_{II})_2\end{Vmatrix}=T\begin{Vmatrix}\bar{E}_1'\\\bar{I}_2'\end{Vmatrix} \tag{59}$$

and

$$\begin{Vmatrix}(\bar{I}_{II})_1\\(\bar{E}_{II})_2\end{Vmatrix}=T\begin{Vmatrix}\bar{I}_1'\\\bar{E}_2'\end{Vmatrix} \tag{60}$$

where for ordinary networks,

$$T=\begin{Vmatrix}\pm1 & 0\\0 & \pm1\end{Vmatrix} \tag{61}$$

This matrix is called the transformation matrix, and the four possible combinations of sign in this matrix represent the four possible subconnections.

If equations 59 and 60 are substituted in equation 48, there results

$$T\begin{Vmatrix}\bar{E}_1'\\\bar{I}_2'\end{Vmatrix}=H_{II}T\begin{Vmatrix}\bar{I}_1'\\\bar{E}_2'\end{Vmatrix} \tag{62}$$

The transformation matrix T is equal to its inverse so that premultiplying equation 62 by the matrix T yields

$$\begin{Vmatrix}\bar{E}_1'\\\bar{I}_2'\end{Vmatrix}=TH_{II}T\begin{Vmatrix}\bar{I}_1'\\\bar{E}_2'\end{Vmatrix} \tag{63}$$

From equations 49, 50, 56, and 57

$$\bar{I}_1'=(\bar{I}_I)_1 \tag{64}$$

$$\bar{E}_2'=(\bar{E}_I)_2 \tag{65}$$

Substitution of equations 55, 58, 64, and 65 in equation 63 yields

$$\begin{Vmatrix}\pm(\bar{E}_{II})_1\\\pm(\bar{I}_{II})_2\end{Vmatrix}=TH_{II}T\begin{Vmatrix}(\bar{I}_I)_1\\(\bar{E}_I)_2\end{Vmatrix} \tag{66}$$

The matrix equation for the subconnections is obtained by adding equations 47 and 66 and substituting equations 51 through 54 into the resulting equation. The following result is obtained

$$\begin{Vmatrix}\bar{E}_1''\\\bar{I}_2''\end{Vmatrix}=(H_I+TH_{II}T)\begin{Vmatrix}\bar{I}_1''\\\bar{E}_2''\end{Vmatrix} \tag{67}$$

Thus, the matrix of the combination network is given by the expression

$$H=H_I+TH_{II}T \tag{68}$$

It can be shown that a similar matrix can be obtained for any one of the other

Vol.
Pt. 1
1959

basic interconnections if the proper matrix relation is used. For example, for the series-series interconnection the impedance matrix becomes

$$Z=Z_I+TZ_{II}T \tag{69}$$

It has already been pointed out that if the networks *I* and *II* represent basic magnetic-amplifier elements, the variable quantities in the foregoing equations are 1×2 submatrices. For magnetic amplifier elements, therefore, the elements in the transformation matrix T (see equation 61) are 2×2 submatrices. For this reason the transformation matrix is written in the form

$$T=\left\|\begin{matrix}\pm X & 0\\ 0 & \pm X\end{matrix}\right\| \tag{70}$$

where the zeros are 2×2 zero submatrices. From the foregoing analysis it may be expected that the matrix X is a 2×2 unit matrix. However, it will be shown that the matrix X also can take the form

$$X=\left\|\begin{matrix}0 & 1\\ 1 & 0\end{matrix}\right\| \tag{71}$$

Practical magnetic amplifiers invariably consist of interconnections of two or more identical basic elements. For two ordinary, linear, identical networks the four possible subconnections reduce to two—subconnections *a* and *b*, for example, in Fig. 4—the other subconnections being identical save for reference directions of the final-network port voltages and currents. For basic magnetic-amplifier elements, however, the four possible subconnections, in general, result in four different magnetic-amplifier circuits even though the two elements are identical, for the following reason. If a d-c signal is applied to the input terminals of basic element *I* in Fig. 5, the saturable inductor of this element saturates during the positive half periods of the supply voltage wave. If the polarity of the input d-c signal is reversed for basic element *II* in Fig. 5, then the saturable inductor of this element saturates during the negative half periods of the supply voltage wave. Thus, if the supply voltage is common to both elements, the inductors of elements *I* and *II* saturate during alternate half periods. For interconnections *c* and *d* in Fig. 4 such a polarity reversal of the input d-c signal is obtained because of the reversal of the input terminals of element *II*. For interconnections *a* and *b*, however, no such reversal exists. Thus, if the supply voltage is common to both elements of the interconnection, the saturable inductors of interconnections *a* and *b* saturate during the same half periods of the supply voltage wave, while the saturable inductors of interconnections *c* and *d* saturate during alternate half periods of the supply voltage wave. This is the property which results in four different magnetic-amplifier circuits for each of the basic interconnections.

The constraints imposed upon the port voltage and currents of the basic elements of interconnections *a* and *b* are (see equations 49 and 50)

$$\left\|\begin{matrix}(E_I)_2^c\\ (E_I)_2^g\end{matrix}\right\|=\pm\left\|\begin{matrix}(E_{II})_2^c\\ (E_{II})_2^g\end{matrix}\right\| \tag{72}$$

and

$$\left\|\begin{matrix}(I_I)_1^c\\ (I_I)_1^g\end{matrix}\right\|=\pm\left\|\begin{matrix}(I_{II})_1^c\\ (I_{II})_1^g\end{matrix}\right\| \tag{73}$$

For subconnections *c* and *d*, however, the control period of element *I* corresponds to the gating period of element *II* and vice versa, so that the constraint equations become

$$\left\|\begin{matrix}(E_I)_2^c\\ (E_I)_2^g\end{matrix}\right\|=\pm\left\|\begin{matrix}(E_{II})_2^g\\ (E_{II})_2^c\end{matrix}\right\| \tag{74}$$

and

$$\left\|\begin{matrix}(I_I)_1^c\\ (I_I)_1^g\end{matrix}\right\|=\pm\left\|\begin{matrix}(I_{II})_1^g\\ (I_{II})_1^c\end{matrix}\right\| \tag{75}$$

Equations 74 and 75 can be rewritten

$$\left\|\begin{matrix}(E_I)_2^c\\ (E_I)_2^g\end{matrix}\right\|=\pm\left\|\begin{matrix}0 & 1\\ 1 & 0\end{matrix}\right\|\left\|\begin{matrix}(E_{II})_2^c\\ (E_{II})_2^g\end{matrix}\right\| \tag{76}$$

and

$$\left\|\begin{matrix}(I_I)_1^c\\ (I_I)_1^g\end{matrix}\right\|=\pm\left\|\begin{matrix}0 & 1\\ 1 & 0\end{matrix}\right\|\left\|\begin{matrix}(I_{II})_1^c\\ (I_{II})_1^g\end{matrix}\right\| \tag{77}$$

If a matrix X is defined so that

$$X=U=\left\|\begin{matrix}1 & 0\\ 0 & 1\end{matrix}\right\| \tag{78}$$

when the two basic elements inductors saturate during the same half periods, and

$$X=\left\|\begin{matrix}0 & 1\\ 1 & 0\end{matrix}\right\| \tag{79}$$

when the two basic elements inductors saturate during alternate half periods, then the constraints imposed upon the port voltages and currents of the basic elements of the subconnections can be expressed in general as follows:

$$(E_I)_2=\pm X(E_{II})_2 \tag{80}$$

$$(I_I)_1=\pm X(I_{II})_1 \tag{81}$$

where the port voltages and currents are 1×2 column matrices representing the division of the operating period into the control and gating periods. The same procedure as used in the derivation of equation 68 can now be followed. The result is

$$H=H_I+TH_IT \tag{82}$$

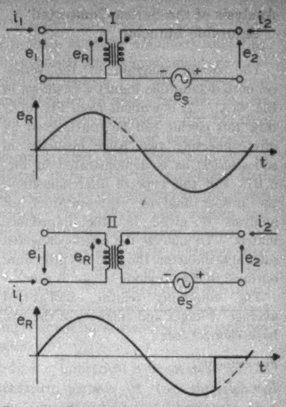

Fig. 5. Saturation during alternate half periods of supply voltage wave

where H is the matrix of the interconnection, H_I is the matrix of the basic element, and T is the transformation matrix

$$T=\left\|\begin{matrix}\pm X & 0\\ 0 & \pm X\end{matrix}\right\| \tag{83}$$

The interchange of control and gating periods considered in the foregoing analysis is caused by the polarity reversal of the applied d-c signal. This polarity reversal is by no means the only factor that causes interchange of control and gating periods. Direct signals at the output port or a 180-degree change in phase of the supply voltage might also cause interchange of control and gating periods. When a particular interconnection is to be studied, all these factors must be taken into account to determine if interchange of control and gating periods occurs.

Interconnections of basic elements that result in interchange of control and gating periods impose an additional restriction upon the voltage waveforms. The matrix addition of equation 82 is valid only if the time periods of elements *I* and *II* in which the average-value quantities are defined coincide; that is, if the control period of element *I* corresponds to the gating period of element *II*, and vice versa. To satisfy this condition it is necessary first to divide the operating period into two equal parts, and second to ensure that the inductor of one element ceases to saturate at the end of the control period of the other element. Clearly, if the waveforms are symmetric, these conditions can be satisfied.

To illustrate the application of the above analysis procedure, the series-connected saturable inductor is analyzed in the next section.

Analysis of the Series-Connected Saturable Inductor

The circuit diagram of the series-connected saturable inductor is shown in Fig. 6(A). It is evident from Fig. 6(A) that this circuit can be constructed by interconnecting two basic elements in series-series, as is demonstrated in Fig. 6(B). For this type of interconnection, the proper analytic representation for analysis is given by the impedance matrix. To analyze the series-connected saturable inductor, the analysis procedure outlined in the previous section is used.

The equations relating half-period average voltages and currents of the two basic elements are:

For element *I*,

$$\bar{E}_I = Z_I \bar{I}_I \tag{84}$$

For element *II*,

$$\bar{E}_{II} = Z_{II} \bar{I}_{II} \tag{85}$$

where the matrices $\bar{E}_I$, $\bar{I}_I$, $\bar{E}_{II}$, and $\bar{I}_{II}$ are 1×4 column matrices of the form

$$\bar{E}_I = \begin{Vmatrix} (\bar{E}_I)_1^c \\ (\bar{E}_I)_1^g \\ (\bar{E}_I)_2^c \\ (\bar{E}_I)_2^g \end{Vmatrix} \tag{86}$$

The two elements are identical so that

$$Z_I = Z_{II} \tag{87}$$

The impedance matrix of the basic element is

$$Z_I = \begin{Vmatrix} R_1+R_m & 0 & R_m & 0 \\ -R_m/z & R_1 & -R_m/z & 0 \\ R_m & 0 & R_2+R_m & 0 \\ -R_m/z & 0 & -R_m/z & R \end{Vmatrix} \tag{88}$$

The next step in the analysis is to determine the transformation matrix *T*. As demonstrated in the previous section, this transformation matrix is uniquely determined by the constraints imposed upon the port voltages and currents of the two elements by the interconnection. Because the input-voltage polarity of element *II* is reversed, the inductors of the two elements saturate during alternate half periods (the subconnection of Fig. 6(B) corresponds to subconnection *c* in Fig. 4 for the series-parallel interconnection). Thus, the control period of element *I* coincides with the gating period of element *II*, and vice versa. The constraint equation becomes

$$\bar{I}_{II} = \begin{Vmatrix} -X & 0 \\ 0 & X \end{Vmatrix} I_I = T I_I \tag{89}$$

where *X* is the submatrix

$$X = \begin{Vmatrix} 0 & 1 \\ 1 & 0 \end{Vmatrix} \tag{90}$$

and *T* the desired transformation matrix.

The following transformation of variables is now made:

$$\bar{E}_{II} = T\bar{E}' \tag{91}$$

$$I_{II} = T\bar{I}' \tag{92}$$

Combining equations 85, 87, 91, and 92 yields

$$T\bar{E}' = Z_I T\bar{I}' \tag{93}$$

The matrix *T* is equal to its inverse so that premultiplying equation 93 by *T* yields

$$\bar{E} = T Z_I T \bar{I}' \tag{94}$$

From equations 89 and 92

$$\bar{I}' = I_I \tag{95}$$

Substitution of equation 95 into equation 94 gives

$$\bar{E}' = T Z_I T \bar{I}_I \tag{96}$$

Addition of equations 84 and 96 gives

$$\bar{E}_I + \bar{E}' = (Z_I + T Z_I T)\bar{I}_I \tag{97}$$

But

$$\bar{E}_I + \bar{E}' = \bar{E}'' \tag{98}$$

$$I_I = \bar{I}'' \tag{99}$$

where the doubled primed quantities are the port voltages and current of the combination network. Thus, substitution of equations 98 and 99 into equation 97 yields the following equation:

$$\bar{E}'' = (Z_I + T Z_I T)\bar{I}'' = Z\bar{I}'' \tag{100}$$

Substitution of equation 88 in equation 100 and performing the matrix operation indicated by equation 100 gives

$$Z = \begin{Vmatrix} 2R_1+R_m & -R_m/z & R_m & R_m/z \\ -R_m/z & 2R_1+R_m & -R_m/z & -R_m \\ R_m & R_m/z & 2R_2+R_m & -R_m/z \\ -R_m/z & -R_m & -R_m/z & 2R_2+R_m \end{Vmatrix} \tag{101}$$

A very interesting property is revealed by equation 101 if the matrix is partitioned into four 2×2 submatrices. The elements along the two principal diagonals of each of these submatrices are seen to be equal in magnitude. If the transforma- is made,

$$\bar{E}'' = A\bar{E}''' \tag{102}$$

$$\bar{I}'' = A\bar{I}''' \tag{103}$$

where

$$A = \begin{Vmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{Vmatrix} \tag{104}$$

the matrix equation, equation 105, is obtained.

$$\begin{Vmatrix} (\bar{E}''')_1^c \\ (\bar{E}''')_1^g \\ (\bar{E}''')_2^c \\ (\bar{E}''')_1^g \end{Vmatrix} = \begin{Vmatrix} 2R_1+R_m & -R_m/z & -R_m & R_m/z \\ -R_m/z & 2R_1+R_m & R_m/z & -R_m \\ -R_m & -R_m/z & 2R_2+R_m & R_m/z \\ -R_m/z & -R_m & R_m/z & 2R_2+R_m \end{Vmatrix} \begin{Vmatrix} (\bar{I}''')_1^c \\ (\bar{I}''')_1^g \\ (\bar{I}''')_2^c \\ (\bar{I}''')_2^g \end{Vmatrix} \tag{105}$$

Addition of the first two and last two rows in equation 105 yields

$$\bar{E}_1 = [2R_1 + R_m(1-1/z)]\bar{I}_1 + R_m(-1+1/z)\bar{I}_2 \tag{106}$$

$$\bar{E}_2 = -R_m(1+1/z)\bar{I}_1 + [2R_2 + R_m(1+1/z)]\bar{I}_2 \tag{107}$$

where

$$\bar{E}_1 = (\bar{E}''')_1^c + (\bar{E}''')_1^g$$

$$\bar{E}_2 = (\bar{E}''')_2^c + (\bar{E}''')_2^g$$

$$\bar{I}_1 = (\bar{I}''')_1^c + (\bar{I}''')_1^g$$

$$\bar{I}_2 = (\bar{I}''')_2^c + (\bar{I}''')_2^g \tag{108}$$

The new variables introduced by equation 108 can be interpreted as follows. The independent current variables with superscript *c* are by definition zero during the gating periods. Similarly, the independent current variables with superscript *g* are by definition zero during the control periods. It is evident from equation 105 that the dependent voltage variables also possess the same property because the terms in the expression for a dependent-voltage variable involving currents of superscripts different from that of the voltage variable are shifted in time one half period. Thus, during the control period

$$\bar{E}_1 = (\bar{E}''')_1^c$$

$$\bar{E}_2 = (\bar{E}''')_2^c$$

$$\bar{I}_1 = (\bar{I}''')_1^c$$

$$\bar{I}_2 = (\bar{I}''')_2^c \tag{109}$$

and during the gating period

$$\bar{E}_1 = (\bar{E}''')_1^g$$

$$\bar{E}_2 = (\bar{E}''')_2^g$$

$$\bar{I}_1 = (\bar{I}''')_1^g$$

$$\bar{I}_2 = (\bar{I}''')_2^g \tag{110}$$

The new variables introduced by equation 108, therefore, are half-period average voltages and currents. These variables are related to the half-period average voltages and currents of the series-connected saturable inductor by a transformation of the type expressed by equations 102 and 103.

The transformation expressed by equations 102 and 103 is fundamental to the analysis of magnetic amplifiers, particularly magnetic amplifiers with diodes. Physically, the transformation can be interpreted as representing the action of a synchronous switch, the switch being operated so that if a d-c signal is applied to it, an a-c output signal is obtained. Or, if an a-c signal is applied, a d-c output signal is obtained. Equation 105, therefore, represents the series-connected saturable inductor in cascade with such a synchronous switch.

If the series-connected saturable inductor is terminated in a linear, passive load, the steady-state output consists of an a-c signal when a d-c signal is applied to the input. This property can be seen from the circuit diagram of Fig. 6. In steady-state operation the voltage across the saturable inductor terminals cannot contain a direct-voltage component. Thus, the voltage across the series combination of the load and the resistance R_2 must be an alternating voltage. The transformation of equations 102 and 103, therefore, can be represented physically as the action of a full-wave rectifier connected to the output terminals. The full wave rectifier renders the series-connected saturable inductor symmetric so that no distinction can be made between the different half periods. The four amplifier equations, therefore, can be reduced to two.

To derive the transfer characteristic of the series-connected saturable inductor with resistive load, the following additional equation is used:

$$E_2 = -R_L I_2 \qquad (111)$$

After equation 111 is substituted into equations 106 and 107 and the resulting equations are solved for E_2 in terms of E_1, equation 112 is obtained by letting R_m tend to infinity and R_2 tend to zero:

$$zE_2 = -\frac{R_L}{R_L+2R_1}(z+1)E_1 + \frac{R_L-2R_1}{R_L+2R_1}E_2 \qquad (112)$$

The inverse Laplace transform of equation 112 produces the same difference equation for the series-connected saturable-inductor circuit as was previously derived by the author.[4]

$$E_2(n+1) = -\frac{R_L}{R_L+2R_1}[E_1(n+1)+E_1(n)] + \frac{R_L-2R_1}{R_L+2R_1}E_2(n) \qquad (113)$$

Since for this type of circuit the magnetizing resistance, R_m, is very large compared with resistance, R_1, and the resistance, R_2, is small compared with load resistance, R_L, the limit process performed in the derivation of equation 112 is applicable to practical circuits.

Interconnection of *n* Basic Elements

The analysis developed previously for a single-phase magnetic amplifier can readily be extended to include the polyphase case. Characteristic of the single-phase amplifier analysis are the division of the operating period into the control and gating periods, and the selection of half-period average voltages and currents as variables. The characteristic equations written then relate variables in the different half periods of operation. Equations written for individual basic elements may be combined in a simple fashion to obtain equations for an interconnection of basic elements, provided that the control and gating periods of the individual elements have the same position in time, or occur so that the control period of one element corresponds to the gating period of the other.

An *n*-phase magnetic amplifier consists of *n* single-phase magnetic amplifiers each connected to one phase of a symmetrical *n*-phase power source. The single-phase amplifiers are usually alike and may consist of one or more cores. The analysis to be presented, however, is not restricted to *n*-phase magnetic amplifiers consisting of *n* identical single-phase amplifiers but is valid in general. If the single-phase amplifiers are all alike, then the analysis can be greatly simplified. For the case of identical single-phase amplifiers in a power system with even numbers of phases, there exists the possibility that the outputs of the individual amplifiers cancel. The analysis still applies and shows that this cancellation occurs. In regard to the steady-state characteristics, it is of interest to note that, if the quiescent currents cancel in the individual single-phase amplifiers, then the *n*-phase amplifier has linear steady-state characteristics.

In a symmetrical *n*-phase system, the operating periods of two single-phase amplifiers in subsequent phases are displaced in time from each other by T/n. The control and gating periods of the individual single-phase amplifiers, therefore, do not have the same position in time nor are they shifted an integral number of half-periods with respect to each other. To overcome this difficulty, it is necessary to divide the control and gating periods into subintervals. In the analysis that follows, it is assumed for an *n*-phase amplifier that each of these periods is divided into *n* subintervals. This subdivision is illustrated in Fig. 7. It may be seen from the figure that the operating periods of the individual single-phase amplifiers are shifted an integral number of subintervals with respect to each other; thus, time coincidence of the subintervals of the various single-phase amplifiers is obtained. The shift between successive phases in Fig. 7 is two subintervals. Therefore, if *n* is even, a possible alternative is to divide the control and gating periods into only *n*/2 subintervals. The larger number, *n*, of subintervals is used so that the

Fig. 7. Division into n subintervals of the control and gating periods of the amplifiers in their successive phases of an n-phase magnetic amplifier

analysis may be applicable whether n is even or odd.

To analyze the n-phase magnetic amplifier, each of the single-phase magnetic amplifiers is described by a set of equations relating average voltages and currents in the various subintervals, the number of equations being four times (two for control and gating subintervals two for input and output ports) the number of subintervals n. For example, in a symmetrical 3-phase system the number of subintervals is three; thus, twelve equations are needed to describe the operation of the individual single-phase amplifiers. The $4n$ equations may be written in matrix form. The matrix of the equations may take any of the forms previously introduced (Y, Z, G, H, or $ABCD$), depending upon which currents and voltages are expressed as functions of the other variables. If, for example, the currents are expressed as functions of the voltages, the admittance matrix

$$Y=\left\|\begin{matrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{matrix}\right\| \qquad (114)$$

is obtained, where each y_{rs} $(r,s=1,2)$ is itself a $2n\times 2n$ matrix relating average values of currents and voltages in the subintervals chosen.

$$y_{rs}=\left\|\begin{matrix} y_{rs}^{c_1c_1}\ldots y_{rs}^{c_1c_n} & y_{rs}^{c_1g_1}\ldots y_{rs}^{c_1g_n} \\ y_{rs}^{c_nc_1}\ldots y_{rs}^{c_nc_n} & y_{rs}^{c_ng_1}\ldots y_{rs}^{c_ng_n} \\ y_{rs}^{g_1c_1}\ldots y_{rs}^{g_1c_n} & y_{rs}^{g_1g_1}\ldots y_{rs}^{g_1g_n} \\ y_{rs}^{g_nc_1}\ldots y_{rs}^{g_nc_n} & y_{rs}^{g_ng_1}\ldots y_{rs}^{g_ng_n} \end{matrix}\right\| \qquad (115)$$

Suppose n single-phase amplifiers each connected to one phase of an n-phase power source are interconnected parallel-parallel. If Y_I, Y_{II}, … Y_N are the admittance matrices for the individual amplifiers, then the equations for these amplifiers become

$$\begin{aligned} I_I &= Y_I\bar{E}_I \\ I_{II} &= Y_{II}\bar{E}_{II} \\ &\cdot\quad\cdot\quad\cdot \\ I_N &= Y_N\bar{E}_N \end{aligned} \qquad (116)$$

where the current and voltage matrices are $1\times 4n$ column matrices.

As seen in Fig. 7, the following subintervals of operation correspond in time:

$$\begin{array}{lllllll} \text{Ampl. } I: & c_1 & c_2 & c_3 & \ldots c_n & g_1 & \ldots g_n \\ \text{Ampl. } II: & g_{n-1} & g_n & c_1 & \ldots c_{n-2} & c_{n-1} & \ldots g_{n-2} \\ \text{Ampl. } III: & g_{n-3} & g_{n-2} & g_{n-1} & \ldots c_{n-4} & c_{n-3} & \ldots g_{n-4} \\ & \cdot & \cdot & \cdot & \cdots\cdot & \cdot & \cdots\cdot \\ \text{Ampl. } N: & c_3 & c_4 & c_5 & \ldots . g_2 & g_3 & \ldots . c_2 \end{array} \qquad (117)$$

Thus, the constraints imposed upon the port voltages by the interconnection are:

$$\begin{aligned} (\bar{E}_I)_s^{c_1} &= (\bar{E}_{II})_s^{g_{n-1}} = (\bar{E}_{III})_s^{g_{n-3}} = \ldots = (\bar{E}_N)_s^{c_3} \\ (\bar{E}_I)_s^{c_2} &= (\bar{E}_{II})_s^{g_n} = (\bar{E}_{III})_s^{g_{n-2}} = \ldots = (\bar{E}_D)_s^{c_4} \\ &\cdot\qquad\cdot\qquad\cdot\qquad\cdots \\ (\bar{E}_I)_s^{g_n} &= (\bar{E}_{II})_s^{g_{n-2}} = (\bar{E}_{III})_s^{g_{n-4}} = \ldots = (\bar{E}_N)_s^{c_2} \end{aligned} \qquad (118)$$

for $s=1$ for input-port voltages, or 2 for output-port voltages. The constraint equations, equation 118, can be written in matrix form as follows:

$$(\bar{E}_I)_s = X(\bar{E}_{II})_s = X^2(\bar{E}_{III})_s = \ldots = X^{n-1}(\bar{E}_N)_s \qquad (119)$$

where the voltage matrices are $1\times 2n$ column matrices of the form

$$(\bar{E}_I)_s=\left\|\begin{matrix} (\bar{E}_I)_s^{c_1} \\ (\bar{E}_I)_s^{c_2} \\ \cdot \\ \cdot \\ \cdot \\ (\bar{E}I)_s^{c_n} \\ (\bar{E}_I)_s^{g_1} \\ \cdot \\ \cdot \\ \cdot \\ (\bar{E}_I)_s^{g_n} \end{matrix}\right\| \qquad (120)$$

For equation 119 to be identical to equation 118, the matrix multiplications shown in equation 119 must move all elements of the $(\bar{E}_{II})_s$ matrix two rows down, all elements of the $(\bar{E}_{III})_s$ matrix four rows down, and so on for the other matrices. If premultiplying a matrix by a matrix X moves all rows two rows down, then it follows that premultiplying a matrix by the square of this matrix moves all rows four rows down. Thus, the form of equation 119 is correct; it only remains to determine a matrix X that performs the above-mentioned transformation. Such a matrix is readily obtained and is as follows:

Vol.
Pt. 1
1959

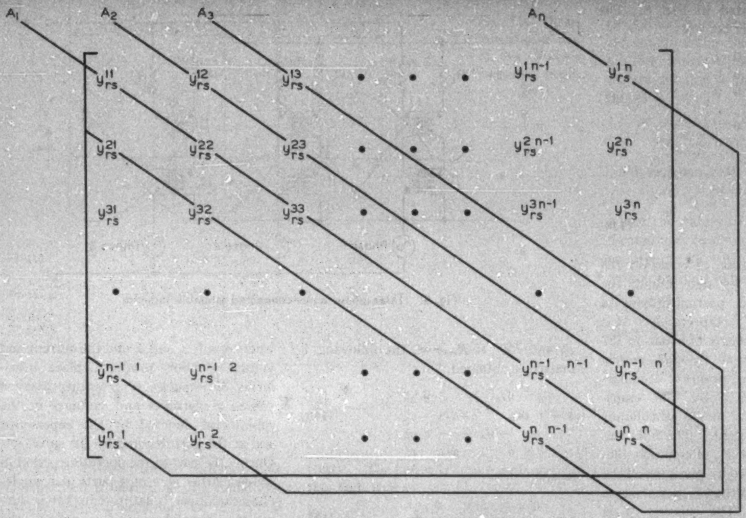

Fig. 8. Addition of matrix components. The elements in the matrix at the left are 2×2 submatrices of the form:

$$y_{rs}=\left\Vert\begin{matrix} y_{rs}^{c1c3} & y_{rs}^{c1c4} \\ y_{rs}^{c2c3} & y_{rs}^{c2c4}\end{matrix}\right\Vert$$

$$X=\left\Vert\begin{matrix} 0 & 0 & . & . & . & & & 1 & 0 \\ 0 & 0 & . & . & . & & & 0 & 1 \\ 1 & 0 & . & . & . & & & 0 & 0 \\ 0 & 1 & 0 & . & . & & & 0 & 0 \\ 0 & 0 & 1 & 0 & . & & & 0 & 0 \\ . & . & . & . & . & & & . & . \\ 0 & 0 & . & . & . & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & . & . & . & & 0 & 1 & 0 & 0 \end{matrix}\right\Vert \qquad (121)$$

In order to derive the matrix relation for the interconnection the following new variables are introduced.

$$\begin{aligned} E_{II}' &= TE_{II} \\ E_{III}' &= T^2E_{III} \\ &\cdot \quad \cdot \quad \cdot \\ E_N' &= T^{n-1}E_N \end{aligned} \qquad (122)$$

and

$$\begin{aligned} I_{II}' &= TI_{II} \\ &\cdot \quad \cdot \quad \cdot \\ I_N' &= T^{n-1}I_N \end{aligned} \qquad (123)$$

where the current and voltage matrices are the 1×4*n* matrices in equation 116, of the form

$$E_{II}=\left\Vert\begin{matrix}(E_{II})_1 \\ (E_{II})_2\end{matrix}\right\Vert \qquad (124)$$

and where

$$T=\left\Vert\begin{matrix}X & 0 \\ 0 & X\end{matrix}\right\Vert \qquad (125)$$

Substitution of equations 122 and 123 into equation 116 yields

$$\begin{aligned} I_I &= Y_IE_I \\ I_{II} &= TY_{II}T_TE_{II}' \\ &\cdot \quad \cdot \quad \cdot \\ I_N' &= T^{n-1}Y_NT_T^{n-1}E_N' \end{aligned} \qquad (126)$$

In the derivation of equation 126 the identity

$$T^{-1}=T_T \qquad (127)$$

is used. The subscript *T* denotes the transpose of a matrix. The validity of equation 127 can be seen from equations 121 and 125, because

$$T_T=\left\Vert\begin{matrix}X & 0 \\ 0 & X\end{matrix}\right\Vert_T=\left\Vert\begin{matrix}X_T & 0 \\ 0 & X_T\end{matrix}\right\Vert \qquad (128)$$

From equation 121

$$X_T=X^{-1} \qquad (129)$$

so that

$$T_T=\left\Vert\begin{matrix}X^{-1} & 0 \\ 0 & X^{-1}\end{matrix}\right\Vert=T^{-1} \qquad (130)$$

It is evident from equations 119, 122, and 125 that the voltage matrices on the right-hand side of equation 126 are equal. Thus, addition of the equations in equation 126 yields

$$I=(Y_I+TY_{II}T_T+\ldots+T^{n-1}Y_NT_T^{n-1})E \qquad (131)$$

where

$$I=I_I+I_{II}'+\ldots+I_N' \qquad (132)$$

$$E=E_I=E_{II}'=\ldots=E_N' \qquad (133)$$

From equations 123, 132, and 133 it is seen that the variables of equation 131 are the port voltages and currents of the final interconnection. Thus, the admittance matrix of the *n*-phase amplifier is given by the expression

$$Y=Y_I+TY_{II}T_T+\ldots+T^{n-1}Y_NT_T^{n-1} \qquad (134)$$

The expressions for the other basic interconnections of *n* single-phase amplifiers can be obtained through a similar procedure.

Most practical polyphase magnetic amplifiers consist of interconnections of identical single-phase amplifiers. These single-phase amplifiers are usually interconnected so that there is no polarity reversal of port voltages of currents. For such polyphase amplifiers, therefore, the matrices of the individual single-phase amplifiers are identical. Under these conditions, equation 134 for the admittance matrix of the parallel-parallel interconnection becomes

$$Y=Y_I+TY_IT_T+\ldots+T^{n-1}Y_IT_T^{n-1} \qquad (135)$$

The matrix summation on the right-hand side of equation 135 can easily be performed, as will be shown next.

Since the transformation matrix *T*, when written as a 2×2 matrix, is a diagonal one, the submatrices Y_{rs} (see equation 114) of the admittance matrix become

$$\begin{aligned} Y_{rs}=(Y_I)_{rs}+X(Y_I)_{rs}X_T+\ldots+ \\ X^{n-1}(Y_I)_{rs}X_T^{n-1} \end{aligned} \qquad (136)$$

where *r* and *s* may each be 1 or 2. To perform the summation of equation 136, the matrices Y_{rs} and $(Y_I)_{rs}$ and the matrix *X* are partitioned into 2×2 submatrices. The partitioning of the admittance matrices is illustrated in Fig. 8. The partitioned X matrix becomes

$$X=\begin{Vmatrix}0 & 0 & \ldots & & 0 & U\\ U & 0 & \ldots & & 0 & 0\\ 0 & U & \ldots & & 0 & 0\\ \cdot & \cdot & & & \cdot & \cdot\\ 0 & 0 & \ldots & U & 0 & 0\\ 0 & 0 & \ldots & 0 & U & 0\end{Vmatrix} \tag{137}$$

where the zeros are 2×2 matrices and U is

$$U=\begin{Vmatrix}1 & 0\\ 0 & 1\end{Vmatrix} \tag{138}$$

The matrix summation of equation 136 can be performed by determining the effect of pre- and postmultiplying a matrix by X and X_T, respectively. It is evident from the matrix of equation 137 that premultiplication by the matrix X moves all rows one row down. Similarly, postmultiplication by the transpose of the matrix X moves all columns one column to the right. The final elements in the matrix Y_{rs} of equation 136, therefore, are obtained by summing all the diagonal elements of the $(Y_I)_{rs}$-matrix, as shown by Fig. 8. The subscript I is omitted in Fig. 8 to simplify the figure. Elements in the same diagonal of the final matrix are identical, and the desired matrix is

$$Y_{rs}=\begin{Vmatrix}A_1 & A_2 & \ldots & A_n\\ A_n & A_1 & \ldots & A_{n-1}\\ \cdot & \cdot & \cdot\ \cdot & \cdot\\ A_3 & A_4 & \ldots & A_2\\ A_2 & A_3 & \ldots & A_1\end{Vmatrix} \tag{139}$$

where each A_i $(i=1, 2 \ldots n)$ is a 2×2 matrix obtained in the manner indicated by Fig. 8.

The procedure described will be demonstrated in the next section by applying it to a 3-phase amplifier.

Analysis of 3-Phase Amplifier

The amplifier to be analyzed, shown in Fig. 9, consists of three series-connected saturable inductors interconnected in parallel-parallel. For the parallel-parallel interconnection the proper analytic representation for analysis is the admittance matrix. The first step in the analysis is to determine the short-circuit driving-point and transfer admittances for the single-phase series-connected saturable inductor. When these admittances have been determined, the 3-phase matrix representation of the individual amplifiers will be derived.

The admittance matrix for the series-connected saturable inductor can be found by inverting the impedance matrix of equation 101. To simplify the expressions, it will be assumed that $R_m >> R_1$ and R_2. If $R_m \rightarrow \infty$, the following Y matrix is obtained

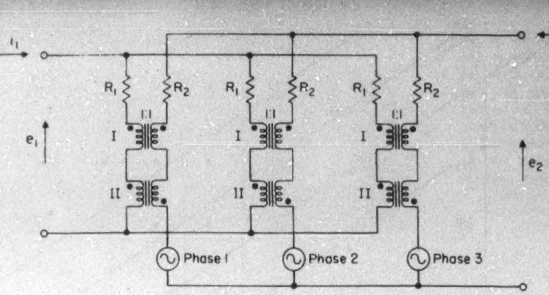

Fig. 9. Three-phase series-connected saturable inductor

$$Y=\begin{Vmatrix}a & b/z & c & d/z\\ b/z & a & -d/z & -c\\ -a & -b/z & -c- & d/z\\ b/z & a & -d/z & -c\end{Vmatrix} \tag{140}$$

where

$$a=\frac{(R_1+R_2)-(R_1-R_2)/z^2}{(R_1+R_2)^2-(R_1-R_2)^2/z^2} \tag{141}$$

$$b=\frac{2R_2}{(R_1+R_2)^2-(R_1-R_2)^2/z^2} \tag{142}$$

$$c=-\frac{(R_1+R_2)+(R_1-R_2)/z^2}{(R_1+R_2)^2-(R_1-R_2)^2/z^2} \tag{143}$$

$$d=-\frac{2R_1}{(R_1+R_2)^2-(R_1-R_2)^2/z^2} \tag{144}$$

To determine the 3-phase matrix representation of the series-connected saturable inductor, it is necessary to establish the subintervals in which saturation of the individual inductors occur. In Fig. 10 these subintervals are shown; in the analysis to be presented the principle mode of operation in which saturation occurs only within the g_3 subinterval of each core in each amplifier is considered. If it is desired to analyze the amplifier when saturation occurs in additional subintervals, e.g., g_2 and g_3 in Fig. 10, a new set of equations must be written.

For the individual amplifiers in the different phases, equations can be written as follows:

$$I_1^{cm}=\sum_{n=1}^{3}\left\Vert y_{11}^{cmcn}E_1^{cn}+y_{11}^{cmgn}E_1^{gn}+y_{12}^{cmcn}E_2^{cn}+y_{12}^{cmgn}E_2^{gn}\right\Vert \tag{145}$$

$$I_1^{gm}=\sum_{n=1}^{3}\left\Vert y_{11}^{gmcn}E_1^{cn}+y_{11}^{gmgn}E_1^{gn}+y_{12}^{gmcn}E_2^{cn}+y_{12}^{gmgn}E_2^{gn}\right\Vert \tag{146}$$

$$I_2^{cm}=\sum_{n=1}^{3}\left\Vert y_{21}^{cmcn}E_1^{cn}+y_{21}^{cmgn}E_1^{gn}+y_{22}^{cmcn}E_2^{cn}+y_{22}^{cmgn}E_2^{gn}\right\Vert \tag{147}$$

$$I_2^{gm}=\sum_{n=1}^{3}\left\Vert y_{21}^{gmcn}E_1^{cn}+y_{21}^{gmgn}E_1^{gn}+y_{22}^{gmcn}E_2^{cn}+y_{22}^{gmgn}E_2^{gn}\right\Vert \tag{148}$$

where $m=1$, 2, and 3, and the current and voltage symbols denote Laplace transforms of impulses representing average values of currents and voltages in the subinterval denoted by the superscript and at the port denoted by the subscript. During the part of the operating period in which neither core of a particular single-phase amplifier is saturated, that is during the intervals c_1, c_2, g_1, and g_2, the driving-point and transfer admittances of that amplifier are zero. Hence, the part currents during these intervals must also be zero.

$$I_1^{c_1}=I_1^{c_2}=I_1^{g_1}=I_1^{g_2}=I_2^{c_1}=I_2^{c_2}=I_2^{gc_1}=I_2^{g_2}=0 \tag{149}$$

To permit the use of the Laplace transform in the analysis of magnetic amplifiers, it was assumed that the variable quantities consist of impulse. It was pointed out that for the purpose of analysis any waveform could be assigned to the variable quantities; the impulse function being chosen for convenience only. For the same reason it is assumed in equations 145 through 149, that the port voltages and currents for the 3-phase amplifier consist of impulses occurring during the subinterval c_1, c_2, c_3 and g_1, g_2, g_3.

The equations for the single-phase

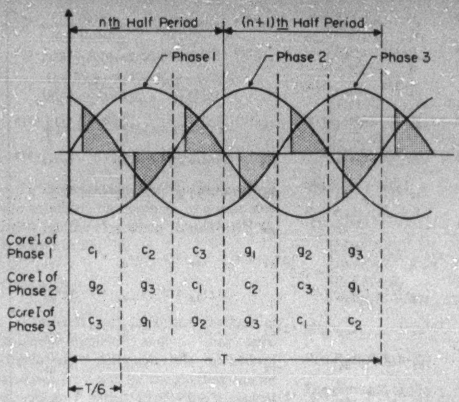

Fig. 10. Intervals of operation of the 3-phase magnetic amplifier

series-connected saturable inductor now can be used to determine the remainder of the port currents for the individual series-connected saturable inductor in the 3-phase system. Suppose that the half-period quantities are represented by impulses that occur during the subinterval c_3 (or g_3), then

$$\bar{I}_1^c=\frac{1}{3}(\bar{I}_1^{c_1}z^{-2/3}+\bar{I}_1^{c_2}z^{-1/3}+\bar{I}_1^{c_3}) \tag{150}$$

where $\bar{I}_1^{c_1}$, $\bar{I}_1^{c_2}$, and $\bar{I}_1^{c_3}$ are the Laplace transform of impulses occurring during the subintervals c_1, c_2, and c_3, respectively. The factor 1/3 takes into account the fact that

$$\bar{I}_1^c$$

is the average current over the complete half period, while

$$\bar{I}_1^{c_1},\ \bar{I}_1^{c_2}, \text{ and } \bar{I}_1^{c_3}$$

are the average currents over the subintervals c_1, c_2, and c_3. Similar relations can also be written for the remainder of the half-period average voltages and currents.

If equation 150 and similar relations for the voltage variables are substituted into the equations for the single-phase amplifier for which equation 140 gives the matrix, the first of the four equations obtained is

$$\begin{aligned}\bar{I}_1^{c_1}z^{-2/3}+\bar{I}_1^{c_2}z^{-1/3}+\bar{I}_1^{c_3}\\ =y_{11}^{cc}(\bar{E}_1^{c_1}z^{-2/3}+\bar{E}_1^{c_2}z^{-1/3}+\bar{E}_1^{c_3})+\\ y_{11}^{cg}(\bar{E}_1^{g_1}z^{-2/3}+\bar{E}_1^{g_2}z^{-1/3}+\bar{E}_1^{g_3})+\\ y_{12}^{cc}(\bar{E}_2^{c_1}z^{-2/3}+\bar{E}_2^{c_2}z^{-1/3}+\bar{E}_2^{c_3})+\\ y_{12}^{cg}(\bar{E}_2^{g_1}z^{-2/3}+\bar{E}_2^{g_2}z^{-1/3}+\bar{E}_2^{g_3})\end{aligned} \tag{151}$$

where the values of the admittances indicated may be determined by comparing equation 140 with equation 40. But from equation 149 both

$$\bar{I}_1^{c_1} \text{ and } \bar{I}_1^{c_2}$$

are zero, thus

$$\begin{aligned}\bar{I}_1^{c_3}=y_{11}^{cc}z^{-2/3}\bar{E}_1^{c_1}+y_{11}^{cc}z^{-1/3}\bar{E}_1^{c_2}+\\ y_{11}^{cc}\bar{E}_1^{c_3}+y_{11}^{cg}z^{-2/3}\bar{E}_1^{g_1}+\\ y_{11}^{cg}z^{-1/3}\bar{E}_1^{g_2}+y_{11}^{cg}\bar{E}_1^{g_3}+\\ y_{12}^{cc}z^{-2/3}\bar{E}_2^{c_1}+y_{12}^{cc}z^{-1/3}\bar{E}_2^{c_2}+\\ y_{12}^{cc}\bar{E}_2^{c_3}+y_{12}^{cg}z^{-1/3}\bar{E}_2^{g_1}+\\ y_{12}^{cg}z^{-1/3}\bar{E}_2^{g_2}+y_{12}^{cg}\bar{E}_2^{g_3}\end{aligned} \tag{152}$$

The remaining three equations obtained from equation 140 lead to similar expressions for

$$\bar{I}_1^{g_3},\ \bar{I}_2^{c_3}, \text{ and } \bar{I}_2^{g_3}$$

In Fig. 11 the complete Y matrix representing the series-connected saturable inductor in a 3-phase system is shown.

The matrix of the interconnected 3-phase amplifier can now be derived by following the procedure outlined in the previous section; the result is shown in Fig. 12. For the present, ignore the signs in parentheses.

Fig. 12 (above). Matrix of 3-phase amplifier

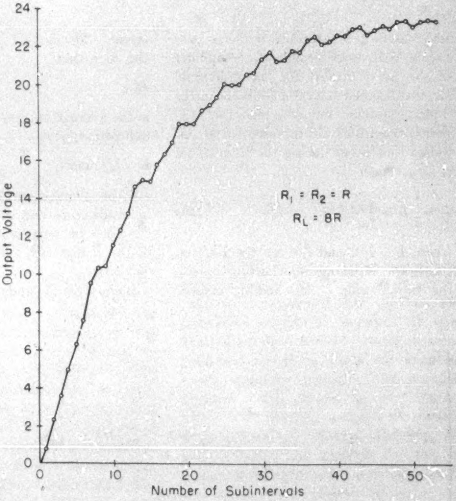

Fig. 13. Unit step response of 3-phase amplifier

In the analysis of the single-phase series-connected saturable inductor, a transformation of variables, physically interpreted as the action of a full-wave rectifier connected to the output, reduced the number of equations describing the operation of the amplifier from four to two. It was pointed out that this reduction was possible, because the action of the full-wave rectifier rendered the circuit symmetric so that no distinction could be made between the two intervals of operation. The same procedure can be applied to the 3-phase amplifier, and the addition of a full-wave rectifier at the output results in the transformation

$$\bar{I} = D\bar{I}' \qquad (153)$$

and

$$\bar{E} = D\bar{E}' \qquad (154)$$

where D is a 12×12 diagonal matrix in which the 8th, 10th, and 12th diagonal elements are -1, and the remaining elements are $+1$. (The first six elements of the $\bar{I}$ and $\bar{E}$ matrices are input quantities and are not changed; the second six are output quantities for the periods c_1, c_2, c_3, g_1, g_2, g_3 and are reversed in alternate periods.) This transformation changes the signs of the matrix coefficients as is shown by the signs in parentheses in Fig. 12. Addition of the six first rows and the six last rows after the transformation is made and substitution of equations 141 through 144 for the constants a, b, c, and d yield the admittance matrix equation:

$$\begin{Vmatrix} \bar{I}_1 \\ \bar{I}_2 \end{Vmatrix} = Y \begin{Vmatrix} \bar{E}_1 \\ \bar{E}_2 \end{Vmatrix} \qquad (155)$$

where Y is the matrix

$$Y = \begin{Vmatrix} \dfrac{1+z^{-1/3}+z^{-2/3}+z^{-1}+z^{-4/3}+z^{-5/3}}{(R_1+R_2)+(R_1-R_2)/z} & -\dfrac{1-z^{-1/3}+z^{-2/3}-z^{-1}+z^{-4/3}-z^{-5/3}}{(R_i+R_2)+(R_1-R_2)/z} \\ -\dfrac{1+z^{-1/3}+z^{-2/3}+z^{-1}+z^{-4/3}+z^{-5/3}}{(R_1+R_2)+(R_1-R_2)/z} & \dfrac{1-z^{-1/3}+z^{-2/3}-z^{-1}+z^{-4/3}-z^{-5/3}}{(R_1+R_2)+(R_1-R_2)/z} \end{Vmatrix} \qquad (156)$$

and

$$\bar{I}_1 = (\bar{I}')_1^{c_1} + (\bar{I}')_1^{c_2} + (\bar{I}')_1^{c_3} + (\bar{I}')_1^{g_1} + (\bar{I}')_1^{g_2} + (\bar{I}')_1^{g_3} \qquad (157)$$

and similarly for $\bar{I}_2$, $\bar{E}_1$, and $\bar{E}_2$. If saturation of the inductors occurs within the specified subintervals, equation 155 completely describes the behavior of the 3-phase amplifier.

To determine the transfer characteristics when resistively loaded, the current $\bar{I}_2$ is eliminated from equation 155 by using the relation $\bar{I}_2 = -(1/R_L)\bar{E}_2$. Then, by taking the inverse Laplace transform of equation 155, the following difference equation is obtained.

$$E_2(n)=\frac{R_L}{R_1+R_2+R_L}[E_1(n)+E_1(n-1/3)+E_1(n-2/3)+E_1(n-1)+E_1(n-4/3)+E_1(n-5/3)+E_2(n-1/3)-E_2(n-2/3)+\left(1-\frac{R_1-R_2}{R_L}\right)E_2(n-1)-E_2(n-4/3)+E_2(n-5/3)] \quad (158)$$

To illustrate the dynamic behavior of the amplifier, the response to a unit step input for the case when $R_1=R_2=1/8\ R_L$ is shown in Fig. 13.

Conclusion

A general and organized method of magnetic-amplifier analysis has been developed. Although this method of analysis may not be the shortest one for a particular circuit, it provides a general means for analysis and gives a clearer insight to the over-all properties of magnetic amplifiers. Magnetic amplifiers with diodes can also be analyzed using the same method, as is demonstrated in reference 2. In particular, this method of analysis is useful in determining general properties of magnetic amplifiers.

Appendix. Matrix Relations for the Basic Magnetic-Amplifier Element

The matrices of equations 43 through 46 are as follows:

$$Z=\begin{Vmatrix} R_1+R_m & 0 & R_m & 0 \\ -R_m/s & R_1 & -R_m/s & 0 \\ R_m & 0 & R_2+R_m & 0 \\ -R_m/s & 0 & -R_m/s & R_2 \end{Vmatrix} \quad (159)$$

$$H=\begin{Vmatrix} R_1+R_3 & 0 & R_m/(R_2+R_m) & 0 \\ -R_3/s & R_1 & -[R_m/(R_2+R_m)]/s & 0 \\ -R_3/R_2 & 0 & 1/(R_2+R_m) & 0 \\ [R_3/R_2]/s & 0 & [R_m/(R_2+R_m)]/R_2s & 1/R_2 \end{Vmatrix} \quad (160)$$

where

$$R_3=R_mR_2/(R_m+R_2) \quad (161)$$

$$G=\begin{Vmatrix} 1/(R_1+R_m) & 0 & R_4/R_1 & 0 \\ R_m/R_1(R_1+R_m)s & 1/R_1 & -R_4/R_1s & 0 \\ R_4/(R_1+R_4) & 0 & R_2+R_4 & 0 \\ -R_4/(R_1+R_4)s & 0 & -R_4/s & R_2 \end{Vmatrix} \quad (162)$$

where

$$R_4=R_mR_1/(R_m+R_1) \quad (163)$$

The elements of the A, B, C, and D matrix are given by the following expressions:

$$A=\begin{Vmatrix} (R_m+R_1)R_m & 0 \\ a/s & 0 \end{Vmatrix} \quad (164)$$

$$B=\begin{Vmatrix} (R_1R_m+R_2R_m+R_1R_2)/R_m & 0 \\ aR_2/s & 0 \end{Vmatrix} \quad (165)$$

$$C=\begin{Vmatrix} 1/R_m & 0 \\ (1+a)/R_1s & 0 \end{Vmatrix} \quad (166)$$

$$D=\begin{Vmatrix} (R_m+R_1)/R_m & 0 \\ R_2(1+a)/R_1s & 0 \end{Vmatrix} \quad (167)$$

where a is an arbitrary constant. The above expressions for A, B, C, and D were determined by solving the original equations. It was found that any value of the constant a will satisfy these equations. The arbitrary nature of a is a result of the property that port voltages and currents during the gating period do not affect port voltages or currents during the control period.

Analysis of Magnetic Amplifiers With Diodes

PAUL R. JOHANNESSEN
ASSOCIATE MEMBER AIEE

IT HAS BEEN demonstrated[1] that the behavior of magnetic amplifiers without diodes can be analytically described by a set of linear difference equations relating the average values of voltages and currents at the ports. For most circuits this representation gives values which are accurate to within 1 or 2% of actual even for a large variety of waveforms of port and supply voltages. The reason for this rather remarkable accuracy of representation can be attributed to three factors:

1. The control circuit resistance R_1, the output circuit resistance R_2, and the load resistance R_L are small compared to the magnetizing resistance R_m.
2. Almost all practical amplifiers of this type employ an interconnection of basic elements such that quiescent currents tend to cancel at the ports.
3. The state of the saturable inductor, saturated or unsaturated, depends on the integral of the inductor voltage rather than the inductor voltage itself.

The first factor insures that the saturable-inductor model is a good approximation to the actual saturable inductor. For all diodeless amplifiers the magnetizing resistance R_M can be considered to be infinite; thus, the ideal saturable-inductor model is sufficient to represent an actual inductor. The second factor insures that changes in the half-period average values of the supply voltage, caused by a shift in the operating period relative to the supply-voltage period, do not cause any steady-state errors in the linear analytic representation. However, the dynamic properties, as predicted by the linear representation, are affected by changes in the half-period average values of the supply voltage. The third

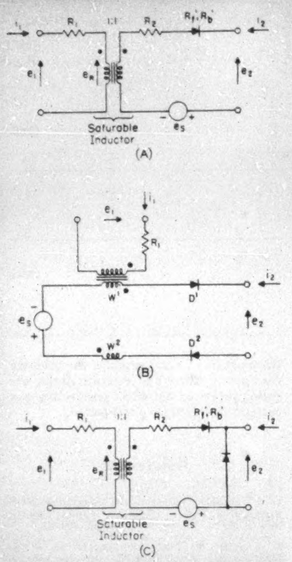

Fig. 1. Basic magnetic amplifiers

factor permits a large variety of waveforms of supply and port voltages to be used without effecting the accuracy of representation.

Magnetic amplifiers with diodes do not possess the aforementioned properties. The back impedance of the diode and the control circuit impedance are usually of the same order of magnitude as the magnetizing impedance. The accuracy of the saturable-inductor model is thus of paramount importance in designing a good analytical model. Cancellation of quiescent currents at the ports caused by interconnection of basic elements is also a property of magnetic amplifiers with diodes; this, however, does not necessarily insure linear steady-state characteristics. Probably the most important factor which distinguishes the behavior of these two types of magnetic amplifiers from each other is the manner in which their operation depends on voltage waveforms. The state of a diode depends upon the instantaneous voltage or current magnitudes while the state of a saturable inductor depends upon the integral of the inductor voltage, which, in turn, may depend upon the state of one diode or the state of several diodes, as well as the supply and port voltages. This interrelation greatly complicates the analysis and necessitates a complete reevaluation of the behavior of the basic elements.

Magnetic amplifiers with diodes invariably consist of symmetrical interconnections of basic elements. Basic elements typical for these types of magnetic amplifiers are shown in Fig. 1. In this paper only element a, of Fig. 1, is analyzed in detail since it is the most common one. Element (B), of Fig. 1, differs from element (A) only in regard to the physical arrangement of components. Thus, the analysis to be performed of element (A) applies equally well to element (B).

Since the objective of this paper is to demonstrate a new method of magnetic-amplifier analysis, the analysis is restricted to magnetic amplifiers terminated in a resistive load, and to voltage waveforms typical of such amplifiers. In the course of the analysis the restrictions upon the voltage waveforms that lead to a linear analysis are established. The voltage waveforms that satisfy these restrictions are termed ideal.

Analysis of Basic Magnetic Amplifier

The basic magnetic amplifier is shown in Fig. 1(A). The diode characteristic is approximated by a piecewise linear curve as shown in Fig. 2, where R_1' is the impedance of the diode when it is conducting and R_b' is the impedance of the diode when it is nonconducting. Two different models of the saturable inductor will be used: one to determine quiescent operating conditions and another to represent the saturable inductor in an incremental linear equivalent circuit. The inductor model which is used to determine the quiescent operating conditions is shown in Fig. 3. The finite loop-width property of the saturable inductor is taken into account by the diode bridge circuit and the constant current source. The diodes in the bridge circuit are assumed to be ideal; that is, having infinite conductance in the forward direction and zero conductance in the reverse direction. In Fig. 4, the complete equivalent circuit of the basic magnetic amplifier to be used in determining the quiescent operating conditions is shown. Use is made of the inequality $R_b' >> R_f'$ in Fig. 4 so that

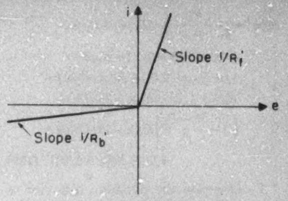

Fig. 2. Diode characteristic

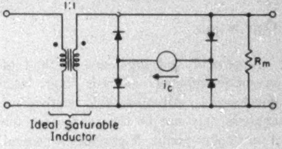

Fig. 3. Saturable inductor model

$$R_b \cong R_b' + R_2$$

$$R_f \cong R_f' + R_2 \qquad (1)$$

States of the Basic Magnetic Amplifier

The possible states of the equivalent circuit of Fig. 4 are shown in Table I. Note that each of the three nonlinear elements in Fig. 4 has two possible states. Combination of these states, therefore, should give rise to eight possible states of the basic magnetic amplifier. However, when the inductor is saturated, the state of the diode bridge is immaterial so that only six different combinations of states exist.

Typical Voltage Waveform

The voltage waveforms typical for magnetic amplifiers terminated in a resistive load are shown in Fig. 5. The voltage e_s passes through zero at time zero with positive slope, is symmetric about the $e=0$ axis, and is periodic of period T. The following approximations can then be made.

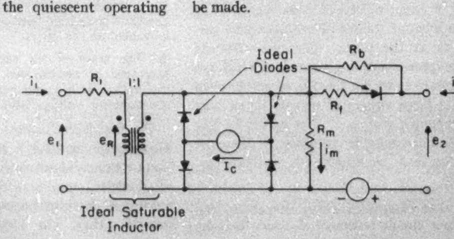

Fig. 4. Equivalent circuit of basic magnetic amplifier

Table I

State	Inductor: Unsaturated	Inductor: Saturated	Diode Bridge: Conductor	Diode Bridge: Nonconductor	Bridge: Conductor	Bridge: Nonconductor	Inductor Voltage

5	1		1			1	0
6	1		1		1		0

$$e_s=\frac{E_s}{T_s}t,\ \text{for } -\Delta t<t<\Delta t \tag{2}$$

$$e_s=-\frac{E_s}{T_s}\left(t-\frac{T}{2}\right),\ \text{for } \frac{T}{2}-\Delta t<t<\frac{T}{2}+\Delta t \tag{3}$$

$$e_s=\frac{E_s}{T_s}(t-T),\ \text{for } T-\Delta t<t<T+\Delta t \tag{4}$$

where

E_s = the half-period average value of the supply voltage
T_s = constant governed by the slope of e_s at a zero crossing

Note that the ratio E_s/T_s is the slope of the e_s wave at a zero crossing. For the same time intervals, the input and output waveforms can be approximated as follows:

$$e_1=E_1'+\frac{E_1}{T_1}t,\ \text{for } -\Delta t<t<\Delta t \tag{5}$$

$$e_1=E_1''-\frac{E_1}{T_1'}\left(t-\frac{T}{2}\right),\ \text{for } \frac{T}{2}-\Delta t<t<\frac{T}{2}+\Delta t \tag{6}$$

$$e_1=E_1'''+\frac{E_1}{T_1''}(t-T),\ \text{for } T-\Delta t<t<\frac{T}{2}+\Delta t \tag{7}$$

and

$$e_2=-\frac{E_2}{T_2}t,\ \text{for } -\Delta t<t<0$$

$$e_2=0,\ \text{for } 0<t<\Delta t \tag{8}$$

$$e_2=\frac{E_2}{T_2}\left(t-\frac{T}{2}\right),\ \text{for } \frac{T}{2}-\Delta t<t<\frac{T}{2}$$

$$e_2=0,\ \text{for } \frac{T}{2}<t<\frac{T}{2}+\Delta t \tag{9}$$

$$e_2=-\frac{E_2}{T_2}(t-T),\ \text{for } T-\Delta t<t<0$$

$$e_2=0,\ \text{for } T<t<T+\Delta t \tag{10}$$

where

E_1', E_1'', and E_1''' = the voltage magnitudes of e_1 at time 0, $T/2$, and T
E_1/T_1, E_1/T_1', and E_1/T_1'' = the magnitudes of the slope of e_1 at time 0, $T/2$, and T
E_2/T_2 = the magnitude of the slope of e_2 just before a zero crossing of the e_s wave

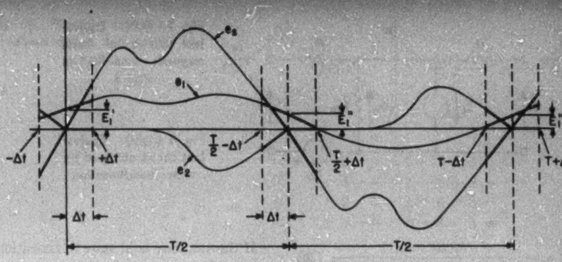

Fig. 5. Voltage waveforms

For reasons of analytical simplicity, all transitions from one state to another are assumed to occur within the time intervals in which the waveform approximations are made. Suppose that at some time t_{-1} in the interval $-\Delta t$ to 0 the inductor is saturated, the diode is conducting, and the operating point P on the inductor characteristic is at point P_{-1} in Fig. 6; saturation thus continues and the inductor voltage, e_R, is zero until the inductor current is equal to I_c. For $t=t_{-1}$, the basic magnetic amplifier is in state 1. In Fig. 6, the state of the amplifier is indicated by the superscripts on the P's. For $t>t_{-1}$, a transition occurs to either state 2 or 3. Transition to state 2 occurs if at some time $t_0>t_{-1}$

$$e_1-R_1I_c<0 \tag{11}$$

$$e_s+e_2=0 \tag{12}$$

For the waveforms chosen it is evident that $t_0=0$. Substitution of the waveform approximation for e_1 in equation 11 yields

$$E_1'<R_1I_c \tag{13}$$

Note that in state 2 the inductor voltage is zero.

If, instead, transition from state 1 to state 3 occurs at some time $t_0'>t_{-1}$, then the following conditions must be satisfied at time $t=t_0'$.

$$e_s+e_2=-\frac{R_f}{R_1}(e_1-R_1I_c) \tag{14}$$

$$e_s+e_2<0 \tag{15}$$

Substitution of equation 15 in equation 14 yields

$$e_1-R_1I_c>0,\ \text{for } t=t_0' \tag{16}$$

or in terms of the approximate voltage waveforms

$$E_1'+\frac{E_1}{T_1}t_0'>R_1I_c \tag{17}$$

As seen from Fig. 5, e_2 is assumed to be less than e_s. This assumption, together with equation 15, leads to a negative value for the time t_0',

$$t_0'<0 \tag{18}$$

From equations 17 and 18

$$E_1'>R_1I_c \tag{19}$$

An expression for t_0' in terms of the approximate waveforms is

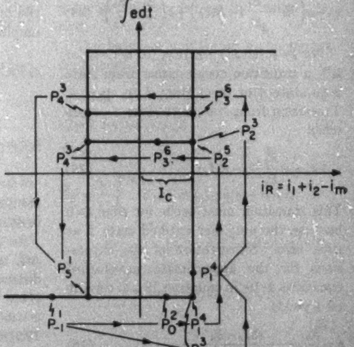

Fig. 6. Inductor characteristic

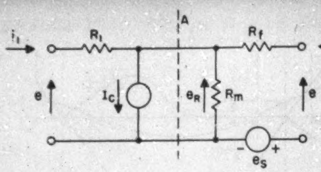

Fig. 7 (left). Equivalent circuit of basic magnetic amplifier in state 3

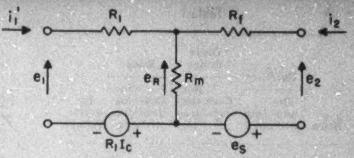
Fig. 8 (right). Equivalent circuit obtained by source transformation



$$t_0'=-\frac{R_f/R_1(E_1'-R_1I_c)}{E_s/T_s-E_2/T_2+(R_f/R_1)(E_1/T_1)} \tag{20}$$

When the amplifier is in state 3, it can be represented by the equivalent circuit of Fig. 7. By use of this equivalent circuit, the inductor voltage can be found in the following manner. If the section of the equivalent circuit on the left side of cut A is transformed into its Thevenin equivalent, the circuit in Fig. 8 results. By inspection of Fig. 8, equation 21 for the inductor voltage is obtained.

$$e_R=a(e_1-R_1I_c)+b(e_s+e_2) \tag{21}$$

where

a = the voltage transfer ratio between the e_1 (or $-R_1I_c$) and e_R (or e_1) terminals (measured with $e_2=e_s=R_1I_c=0$) when the diode is conducting

b = the voltage transfer ratio between the e_s (or e_2) and e_R terminals (measured with e_2 (or e_s) $=e_1=R_1I_c$ (or $e_1-R_1I_c$) $=0$) when the diode is conducting

In terms of the circuit parameters, the expressions for a and b are

$$a=\frac{R_mR_f}{R_1R_m+R_1R_f+R_mR_f} \tag{22}$$

$$b=\frac{R_mR_1}{R_1R_m+R_1R_f+R_mR_f}=a\frac{R_1}{R_f} \tag{23}$$

In terms of the approximate waveforms the expression for the inductor voltage then becomes

$$e_R=a\left(E_1'+\frac{E_1}{T_1}t-R_1I_c\right)+b\left(\frac{E_s}{T_s}-\frac{E_2}{T_2}\right)t \tag{24}$$

For $t=t_1$ (or t_1') where t_1 (or t_1')$>t_0$ (or t_0'), a transition occurs either from state 2 to state 4 or from state 3 to state 4. Transition from state 2 to state 4 occurs when

$$e_s+e_2=-\frac{R_b}{R_1}(e_1-R_1I_c) \tag{25}$$

This transition must occur for time $t>0$ because the amplifier entered state 2 at time zero. Substitution of the expressions for the approximate waveforms, equations 2–10, in equation 25 and solving for t_1 yields

$$t_1=\frac{R_b}{R_1}\frac{R_1I_c-E_1'}{E_s/T_s+(R_b/R_1)(E_1/T_1)} \tag{26}$$

If the amplifier is in state 3, transition to state 4 occurs at time t_1' when

$$e_s+e_2=\frac{R_m}{R_1+R_m}(e_1-R_1I_c) \tag{27}$$

In state 3 the inductor voltage is positive. Thus, the instant of time t_1' must occur after $t=0$. Substituting the approximate expressions for the voltage waveforms in equation 27 and solving for t_1' gives

$$t_1'=\frac{R_m}{R_1+R_m}\frac{E_1'-R_1I_c}{E_s/T_s-\dfrac{R_m}{R_1+R_m}E_1/T_1} \tag{28}$$

The equivalent circuit of the amplifier in state 4 is the same as that of Fig. 8, state 3, except that the diode resistance is R_b instead of R_f. The inductor voltage in state 4 thus becomes

$$e_r=c(e_1-R_1I_c)+d(e_s+e_2) \tag{29}$$

where the constants c and d are voltage transfer ratios similar to a and b in equation 21 except that the diode in nonconducting instead of conducting. In terms of the circuit parameters expressions for c and d are

$$c=\frac{R_mR_b}{R_1R_m+R_1R_b+R_mR_b} \tag{30}$$

$$d=\frac{R_mR_1}{R_1R_m+R_1R_b+R_mR_b}=c\frac{R_1}{R_b} \tag{31}$$

The transitions discussed in the foregoing are assumed to take place within the interval $-\Delta t$ to Δt. At time Δt the amplifier is in state 4. If the conditions

$$e_s+e_2>-\frac{R_b}{R_1}(e_1-R_1I_c),\ \text{for}\ \Delta t<t<\frac{T}{2}-\Delta t \tag{32}$$

$$e_s+e_2>\frac{R_m}{R_1+R_m}(e_1-R_1I_c),\ \text{for}\ \Delta t<t<\frac{T}{2}-\Delta t \tag{33}$$

are satisfied, then the amplifier remains in state 4.

In the interval $(T/2-\Delta t)$ to $(T/2+\Delta t)$, transitions similar to those already discussed for the interval $-\Delta t$ to Δt take place. If the inequality of equation 32 is violated in the interval $(T/2-\Delta t)$ to $T/2$, then transition to state 5 occurs at time

$$t_2=\frac{T}{2}-\frac{R_b}{R_1}\frac{R_1I_c-E_1''}{E_s/T_s-E_2/T_2+(R_b/R_1)(E_1/T_1')} \tag{34}$$

Note that state 5 and state 1 are equivalent in as far as current and voltage relations are concerned. If the inequality of equation 33 is violated, then transition to state 3 occurs at time

$$t_2'=\frac{T}{2}-\frac{R_m}{R_1+R_m}\times\frac{E_1''-R_1I_c}{E_s/T_s-E_2/T_2-\dfrac{R_m}{R_1+R_m}E_1/T_1'} \tag{35}$$

Note that t_2' must occur before $T/2$. In state 3 the inductor voltage is given by equation 21.

Next, transition from state 5 or 3 to state 6 occurs. If the amplifier is in state 5, then transition to state 6 occurs at time

$$t_3=T/2 \tag{36}$$

If the waveform of e_1 had been chosen so that E_1'' is negative, then the transition from state 5 to state 6 may occur after time $T/2$. This event takes place if $-E_1''>R_1I_c$. Thus, if $-R_1I_c<E_1''<R_1I_c$, then transition to state 6 occurs at time $t_3=T/2$.

If the amplifier is in state 3, then transition to state 6 occurs when

$$e_s+e_2=-\frac{R_f}{R_1}(e_1-R_1I_c) \tag{37}$$

In state 3 the diode is conducting; the inductor voltage must then be greater than e_s+e_2. Thus the time of transition from state 3 to state 6 occurs after time $T/2$, and is given by the expression

$$t_3'=T/2+\frac{R_f}{R_1}\frac{E_1''-R_1I_c}{E_s/T_s+(R_f/R_1)(E_1/T_1')} \tag{38}$$

The next transition is from state 6 to state 3 and occurs when

$$e_1+e_2=-\frac{R_f}{R_1}(e_1+R_1I_c) \tag{39}$$

and at time

$$t_4=T/2+\frac{R_f}{R_1}\frac{E_1''+R_1I_c}{E_s/T_s+(R_f/R_1)(E_1/T_1')} \tag{40}$$

The inductor voltage for state 3 is supposedly given by equation 21. This equation was derived for the operating point P_0^3 in Fig. 6. For the present case the operating point is on the other side of the inductor characteristic. Thus, for the present case, the current source I_c in the equivalent circuit of Fig. 7 is of opposite polarity so that the term $e_1 - R_1 I_c$ in the equation for the inductor voltage becomes $e_1 + R_1 I_c$. For the amplifier to remain in state 3 until the inductor saturates at t_6, $e_s + e_2$ must satisfy both of the following inequalities

$$e_s + e_2 < -\frac{R_f}{R_1}(e_1 + R_1 I_c) \tag{41}$$

$$e_s + e_2 < \frac{R_m}{R_1 + R_m}(e_1 + R_1 I_c) \tag{42}$$

Equation 41 insures that the net inductor current is greater than I_c, while equation 42 insures that the diode conducts. For the waveforms of Fig. 5, equation 41 is satisfied if equation 42 is satisfied. When the inductor saturates at time t_6, transition to state 1 occurs and saturation continues until a new period of operation starts. It is evident that the sequence of transitions taking place in the next period of operation may not be the same as in the period just considered. However, if all voltage waveforms are periodic, then the sequence of transitions are the same for all periods of operation.

A diagram illustrating the possible sequences of transitions that may occur during one period of operation is shown in Fig. 9. These sequences of transitions are the only ones that can occur for voltage waveforms of the type shown in Fig. 5 that satisfy equations 32, 33, 41, and 42. Clearly, for voltage waveforms different from those shown in Fig. 5 that may or may not satisfy equations 32, 33, 41, and 42, there exists a large number of possible sequences of transitions. It is beyond the scope of this work to consider all of these possibilities.

The waveforms of Fig. 5 were chosen in order to demonstrate a method of analysis and to establish restrictions upon the voltage waveforms that render the equations for the basic amplifier linear. To establish these waveform restrictions, the amplifier equations for the four sequences of transitions in Fig. 9 must be studied. In Appendix I the amplifier equations for sequence of transitions c are derived, and it is shown that these equations are linear if either of the two equations, 163 and 164, together with equations 32, 33, and 42, are satisfied for all periods of operations.

The conditions of equation 164 may appear to be trivial, since they imply that all the voltage waves are constant near the zero crossings of the e_s wave. The author, however, has not been able to derive the linearization conditions of equations 163 and 164 without going through the detailed study of possible sequences of transitions as given in this section and the derivation of the amplifier equations as presented in Appendix I. It is further shown in Appendix I that if these waveform restrictions are satisfied, then the amplifier equations are linear for all four sequences of transitions.

Equations 163 and 164 are not the only linearization conditions that exist. A general study of all possible relations between the various voltage waveforms that render the amplifier equations linear appears to be of little practical value. The conditions of equations 163 and 164, however, are often met in practical amplifiers. The linearization condition of equation 163 is of special interest since considerable freedom is allowed for the various voltage waveforms. This condition, together with the conditions of equations 32, 33, and 42, may be formulated in terms of four alternate conditions as follows:

1. The operation of the amplifier must be periodic and of the same period as the supply voltage.
2. The diode must be nonconducting during the control periods and conducting during the gating periods.
3. The inductor voltage must be positive during the control periods.
4. The input voltage must satisfy the relation.

$$e_1 = R_1 I_c, \text{ for } t = T/2 \tag{43}$$

These conditions need not be satisfied in order to perform a linear, small-signal analysis around the quiescent operating point. This type of analysis is most easily performed by first determining the quiescent operating conditions, as outlined in Appendix I for the combination of transitions c in Fig. 9, and then linearizing around the quiescent operating point.

Fig. 9. Possible sequences of transitions during one period of operation

CIRCUIT EQUATIONS FOR BASIC MAGNETIC AMPLIFIERS THAT SATISFY THE FIRST THREE LINEARIZATION CONDITIONS

In basic magnetic amplifiers that satisfy conditions 1, 2, and 3, there exist two possible sequences of transitions:

(1) 1−4−5−6−3−1

(2) 1−4−6−3−1

Only sequence 1 need be considered because sequence 2 is actually a special case of 1 for which the time spent in state 5 zero.

During the control period, the following equations hold,

$$E_1^c = R_1 I_1^c + E_R^c \tag{44}$$

$$E_s^c + E_2^c = R_b I_2^c + E_R^c \tag{45}$$

and during the gating period

$$E_1^g = R_1 I_1^g + E_R^g \tag{46}$$

$$E_s^g + E_2^g = R_f I_2^g + E_R^g \tag{47}$$

For the foregoing, the notation is the same as used in reference 1. To obtain four equations involving the eight port voltages and currents only, two more equations are needed. One of these equations is the well-known relation

$$E_R^c + E_R^g = 0 \tag{48}$$

the other is obtained by calculating the inductor voltage during the control period.

The inductor voltage is given by the expressions

$$e_R = c(e_1 - R_1 I_c) + d(e_s + e_2), \text{ for } 0 < t < t_2 \tag{49}$$

$$e_R = 0, \text{ for } t_2 < t < T/2 \tag{50}$$

Thus,

$$\begin{aligned} E_R^c &= \frac{2}{T}\int_0^{t_2} [c(e_1 - R_1 I_c) + d(e_s + e_2)]\,dt \\ &= \frac{2}{T}\int_0^{T/2} [c(e_1 - R_1 I_c) + d(e_s + e_2)]\,dt - \\ &\quad \frac{2}{T}\int_{t_2}^{T/2} [c(e_1 - R_1 I_c) + d(e_s + e_2)]\,dt \end{aligned} \tag{51}$$

which, when integrated, gives

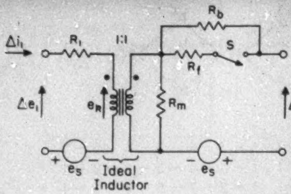

Fig. 10. Linear incremental model of basic magnetic amplifier

$$E_R{}^c = c(E_1{}^c - R_1I_c) + c\frac{R_1}{R_b}(E_s{}^c + E_2{}^c) + \frac{1}{T}\frac{R_b}{R_1}c\frac{1}{A_s - A_2 + (R_b/R_1)A_1{}'}(E_1{}'' - R_1I_c)^2 \qquad (52)$$

where

$A_s = E_s/T_s$ = the magnitude of the slope of the e_s wave at time $T/2$

$A_2 = E_2/T_2$ = the magnitude of the slope of the e_s wave immediately before time $T/2$

$A_1{}' = E_1/T_1{}'$ = the magnitude of the slope of the e_1 wave at time $T/2$

If the slopes A_s, A_2, and $A_1{}'$, and the voltage $E_1{}''$ are independent of the half-period average values of the voltages and currents at ports 1 and 2, and if the supply voltage is constant, then equation 52 can be rewritten

$$E_R{}^c = cE_1{}^c + d(E_s{}^c + E_2{}^c) - B \qquad (53)$$

where B is a constant given by the expression

$$B = cR_1I_c - \frac{1}{T}\frac{R_b}{R_1}c\frac{(E_1{}'' - R_1I_c)^2}{A_s - A_2 + (R_b/R_1)A_1{}'} \qquad (54)$$

If $E_1{}'' = R_1I_c$, then $E_R{}^c$ is independent of the slopes A_s, A_2, and $A_1{}'$, and the expression for B becomes simply

$$B = cR_1I_c \qquad (55)$$

This is the special case for which the sequence of transition 2 applies.

Substitution of equations 48 and 53 in equations 44, 45, 46, and 47, with an appropriate rearrangement of terms, yields the admittance-matrix equation of the amplifier.

$$\left\|\begin{matrix} I_1{}^c \\ I_1{}^g \\ I_2{}^c \\ I_2{}^g \end{matrix}\right\| = \left\|\begin{matrix} \frac{1-c}{R_1} & 0 & -\frac{d}{R_1} & 0 & -\frac{d}{R_1} & 0 \\ \frac{c}{R_1} & \frac{1}{R_1} & \frac{d}{R_1} & 0 & \frac{d}{R_1} & 0 \\ -\frac{c}{R_b} & 0 & \frac{1-d}{R_b} & 0 & \frac{1-d}{R_b} & 0 \\ \frac{c}{R_f} & 0 & \frac{d}{R_f} & \frac{1}{R_f} & \frac{d}{R_f} & \frac{1}{R_f} \end{matrix}\right\| \left\|\begin{matrix} E_1{}^c \\ E_1{}^g \\ E_2{}^c \\ E_2{}^g \\ E_s{}^c \\ E_s{}^g \end{matrix}\right\| + \beta \qquad (56)$$

where B is the column matrix

$$\beta = \left\|\begin{matrix} \frac{1}{R_1}B \\ -\frac{1}{R_1}B \\ -\frac{1}{R_b}B \\ \frac{1}{R_f}B \end{matrix}\right\| \qquad (57)$$

More generally, any desired network matrix can be obtained from these same equations.

Incremental Linear Analysis

Suppose that the half-period average voltages and currents of equation 56 are the quiescent currents and voltages, then the admittance-matrix equation which relates the Δ quantities at ports 1 and 2 is

$$\left\|\begin{matrix} \Delta I_1{}^c \\ \Delta I_1{}^g \\ \Delta I_2{}^c \\ \Delta I_2{}^g \end{matrix}\right\| = \left\|\begin{matrix} \frac{1-c}{R_1} & 0 & -\frac{d}{R_1} & 0 \\ \frac{c}{R_1} & \frac{1}{R_1} & \frac{d}{R_1} & 0 \\ -\frac{c}{R_b} & 0 & \frac{1-d}{R_b} & 0 \\ \frac{c}{R_f} & 0 & \frac{d}{R_f} & \frac{1}{R_f} \end{matrix}\right\| \left\|\begin{matrix} \Delta E_1{}^c \\ \Delta E_1{}^g \\ \Delta E_2{}^c \\ \Delta E_2{}^g \end{matrix}\right\| \qquad (58)$$

In general, this equation is valid only if the Δ quantities result from incremental changes in the waveforms of the quiescent currents and voltages. Thus, equation 58 is a linear relation among incremental deviations from the quiescent condition. It is of importance to point out that the restriction of small changes in the average values of the port quantities is not always necessary. If the changes in the waveforms are such that the total voltage waves at ports 1 and 2 satisfy the conditions for ideal waveforms, then the amplifier is linear and is represented by equation 58.

A linear-incremental circuit model of the basic magnetic amplifier is shown in Fig. 10. The switch S is open during the positive half periods and closed during the negative half periods of e_s.

In the preceding analysis, it was found that, in general, the amplifier equations are not linear. The nonlinearity in the equations is introduced by the last term of equation 52 and is caused by changes in the slopes of the voltage waves near the zero crossings of the e_s wave and the quantity $E_1{}''$ with applied signals. For practical amplifiers terminated in a resistive load, the slope of the output voltage wave near the zero crossings of the e_s wave is governed by the e_s wave only. This is true in general for single-phase amplifiers terminated in a resistive load; for 3-phase amplifiers, however, this is true only if the amplifier operates in mode 1 and is resistively loaded. If the e_s wave is assumed to be invarient, then the following analysis can be made. Let

$$A_q = A_{sq} - A_{2q} + (R_b/R_1)A_1{}'_q \qquad (59)$$

where the subscript q indicates the quiescent condition. Changes in $E_R{}^c$ caused by changes in $E_1{}^c$ and $E_2{}^c$ can then be written

$$\begin{aligned} \Delta E_R{}^c &= E_R{}^c{}_q + \Delta E_R{}^c - E_R{}^c{}_q \\ &= c(E_1{}^c{}_q + \Delta E_1{}^c - R_1I_c) + \\ &\quad d(E_s{}^c{}_q + E_2{}^c{}_q + \Delta E_2{}^c) + \\ &\quad \frac{1}{T}\frac{R_b}{R_1}c\frac{(E_1{}''{}_q + \Delta E_1{}'' - R_1I_c)^2}{A_q + \Delta A} - \\ &\quad c(E_1{}^c{}_q - R_1I_c) - d(E_s{}^c{}_q + E_2{}^c{}_q) - \\ &\quad \frac{1}{T}\frac{R_b}{R_1}c\frac{(E_1{}''{}_q - R_1I_c)^2}{A_q} \end{aligned} \qquad (60)$$

For small Δ changes the following approximation can be made

$$\frac{1}{A_q + \Delta A} \cong \frac{1}{A_q}\frac{1}{1 + \frac{\Delta A}{A_q}} = \frac{1}{A_q}\left(1 - \frac{\Delta A}{A_q}\right) \qquad (61)$$

Substitution of equation 61 in equation 60 and cancellation of all Δ^2 terms yield

$$\Delta E_R{}^c = c\Delta E_1{}^c + d\Delta E_2{}^c + \frac{1}{T}\frac{R_b}{R_1}c\cdot\frac{2}{A_q}(E_1{}''{}_q - R_1I_c)\Delta E_1{}'' - \frac{1}{T}c\left(\frac{R_b}{R_1}\right)^2\left(\frac{1}{A_q}\right)^2(E_1{}''{}_q - R_1I_c)^2\Delta A \qquad (62)$$

The quantity $\Delta E_1{}''$ is the change in the magnitude of the e_1 wave at time $T/2$. Usually, $\Delta E_1{}''$ is linearly related to $\Delta E_1{}^c$, $E_1{}''$ is equal to $E_1{}^c$ for direct current, and is zero for a full-wave rectified sine wave. Let

$$\Delta E_1{}'' = K_1\Delta E_1{}^c \qquad (63)$$

where K_1 is a constant.

The quantity ΔA is the change in the slope of the e_1 wave at time $T/2$. Clearly, if the waveform of e_1 is fixed and only the magnitude is varied, then

$$\Delta A=\frac{1}{T_1'}\Delta E_1^c \qquad (64)$$

where T_1' is a constant. Substitution of equations 63 and 64 in equation 62 yields

$$\Delta E_R^c=c'\Delta E_1^c+d\Delta E_2^c \qquad (65)$$

where

$$c'=c\left\{1+\frac{1}{T}\frac{R_b}{R_1}\frac{1}{A_q}(E_1''_q-R_1I_c)\times\right.$$
$$\left.\left[2K_1-\frac{1}{T_1'}\frac{R_b}{R_1}\frac{1}{A_q}(E_1''_q-R_1I_c)\right]\right\} \qquad (66)$$

Equation 65, together with equations 44, 45, 46, 47, and 48, leads again to a linear analysis of the basic magnetic amplifier in terms of incremental deviation from the quiescent condition.

It is evident from equation 66 that, for the special cases in which either A_q is infinite, that is, if either of the slopes A_{sq} and $A_1'_q$, or both, are infinite, or E_1'' is equal to R_1I_c, the quantity c' reduces to c.

The preceding considerations hold not only for incremental deviations from the quiescent condition but also for incremental deviations from any predetermined operating condition.

BIAS CONSIDERATIONS

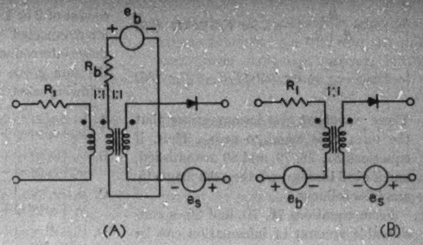
In most practical amplifiers a bias, or reset, circuit is provided to adjust the quiescent operating condition as desired. This is accomplished either by an additional bias winding on the inductor connected in series with a resistor and a voltage source or by a voltage source in series with the input. These two methods of obtaining the proper bias are shown in Fig. 11 and are referred to as parallel and series bias, respectively. The voltage gain of the amplifier is proportional to the component of the inductor voltage cE_1^c, where the voltage transfer ratio c is given by equation 30. In the case of parallel bias, the resistance R_b effectively shunts the inductor and thus decreases the value of the voltage transfer ratio c, which, in turn, decreases the voltage gain. It is thus desirable to make the resistance R_b as large as possible. In the limiting case when R_b approaches infinity, the resistance R_b and the voltage source e_b can be replaced by a constant current source i_b. This current source, by Thevinin's theorem, is equivalent to a voltage source of magnitude R_1i_b in series with the input voltage. Thus the two bias methods become identical and no loss in gain results. If

$$e_b=R_1I_c \qquad (67)$$

then the bias voltage cancels the equivalent voltage source R_1I_c during the control periods. Effectively, this bias voltage shifts the hysteresis loop in Fig. 6 to the left by an amount I_c so that the apparent loop width is zero during the control periods and equal to $2I_c$ during the gating periods.

Fig. 11. Bias methods

A—Parallel
B—Series



With a bias voltage, or current, in the amplifier, the ideal waveform restrictions are altered slightly. When the bias voltage is equal to R_1I_c, these restrictions become

$$E_1'=E_1''=E_1'''=0 \qquad (68)$$

$$e_s+e_2>\frac{R_m}{R_1+R_m}e_1,\ \text{for } 0<t<\frac{T}{2} \qquad (69)$$

$$e_s+e_2<\frac{R_m}{R_1+R_m}(e_1+2R_1I_c),\ \text{for } \frac{T}{2}<t<t_5 \qquad (70)$$

$$e_s+e_2>-\frac{R_b}{R_1}e_1,\ \text{for } 0<t<T/2 \qquad (71)$$

The expression for the term B in the equation for the inductor voltage, equation 53, becomes

$$B=-\frac{1}{T}\frac{R_b}{R_1}c\frac{(E_1'')^2}{A_s-A_2+(R_b/R_1)A_1'} \qquad (72)$$

From the relation

$$E_2^g=R_fI_2^g-E_R^c-E_s^g \qquad (73)$$

obtained by substituting equation 48 in equation 47, it is evident that the relation between the port quantities E_2^g and I_2^g does not depend upon the inductor characteristics during the gating periods. In fact, any finite resistance can be placed across the inductor during the gating periods without affecting the performance of the amplifier. In addition, if the bias voltage is equal to R_1I_c, the apparent loop width is equal to zero during the control periods. Thus, for ideal waveforms and the bias voltage of equation 67, the amplifier is linear and independent upon the constant loop-width property of the saturable inductor. For this reason, the bias voltage of equation 67 is termed the ideal.

A SET OF IDEAL VOLTAGE-WAVEFORM RESTRICTIONS

To study voltage waveforms in practical amplifiers, a set of sufficient, although not necessary, restrictions upon the voltage waveforms for the case when

$$e_s+e_2>0,\ \text{for } 0<t<\frac{T}{2}$$

$$e_s+e_2<0,\ \text{for } \frac{T}{2}<t<T \qquad (74)$$

are derived from the waveform restrictions of equations 68 through 71 as follows.

From equation 74,

$$e_s+e_2=|e_s+e_2|,\ \text{for } 0<t<\frac{T}{2} \qquad (75)$$

Thus, if

$$|e_s+e_2|>\frac{R_m}{R_1+R_m}e_1,\ \text{for } 0<t<\frac{T}{2} \qquad (76)$$

then equation 69 is satisfied.

Equation 70 can be alternatively written

$$-(e_s+e_2)>-\frac{R_m}{R_1+R_m}(e_1+2R_1I_c),$$
$$\text{for } \frac{T}{2}<t<t_5 \qquad (77)$$

From equation 74,

$$-(e_s+e_2)=|e_s+e_2|,\ \text{for } \frac{T}{2}<t<T \qquad (78)$$

Thus, if

$$|e_s+e_2|>\frac{R_m}{R_1+R_m}(-e_1),\ \text{for } \frac{T}{2}<t<t_5 \qquad (79)$$

then equation 70 is satisfied.

Through a similar derivation,

$$|e_s+e_2|>-\frac{R_b}{R_1}e_1,\ \text{for } 0<t<T/2 \qquad (80)$$

then equation 71 is satisfied. Thus, a set of sufficient, but not necessary, restrictons upon the voltage waveforms is

$$E_1'=E_1''=E_1'''=0 \qquad (81)$$

$$|e_s+e_2|>\frac{R_m}{R_1+R_m}e_1,\ \text{for } 0<t<T/2 \qquad (76)$$

$$|e_s+e_2| > \frac{R_m}{R_1+R_m}(-e_1), \text{ for } T/2<t<t_b \qquad (79)$$

$$|e_s+e_2| > -\frac{R_b}{R_1}e_1, \text{ for } 0<t<T/2 \qquad (80)$$

These waveform restrictions insure that the term B is equal to zero. Thus, if equations 81, 76, 79, and 80 are satisfied, and if ideal bias is used, then the magnetic amplifier is linear.

From equations 76, 79, and 80, a considerable amount of information can be obtained regarding the behavior of single-phase magnetic amplifiers terminated in a resistive load. Equation 76 essentially states that the maximum inductor voltage that can exist during the control periods without causing the diode to conduct is equal to the sum of the supply voltage and the output voltage. Because the inequality

$$R_1 >> R_f$$

usually is satisfied, the sum of the supply and output voltages establishes an upper limit on the inductor voltage during a control period. This limit, in turn, establishes an upper limit on the maximum flux reset that can occur during a control period. If equation 79 is satisfied, the diode is conducting and the component of the inductor voltage caused by the input voltage is small. Thus, the inductor is driven toward saturation by the supply and output voltages. However, if the input voltage is large and negative, such that equation 79 is not satisfied, then the diode is nonconducting and the input voltage is effective in driving the inductor toward saturation. In conclusion, it apparently is relatively easy to prevent the inductor from being reset during a control period and to drive the inductor toward saturation during a gating period. Difficulties may arise in attempting to reset the inductor during a control period and in preventing it from being driven toward saturation during a gating period. It may be said that the inductor "likes" to be saturated.

This property is basically responsible for several undesirable magnetic-amplifier limitations: the low-efficiency of all fast-response magnetic amplifiers; the impossibility of constructing a full-wave polarity-reversible d-c amplifier of greater than 50% efficiency; and the impossibility of constructing a fast-response, highly efficient magnetic amplifier with full-wave a-c output.

THE VOLTAGE e_s+e_2 IN PRACTICAL MAGNETIC AMPLIFIERS

A single-phase magnetic amplifier may consist of 2 or 4 basic magnetic amplifiers interconnected in various ways. For these interconnections the magnitude of the sum e_s+e_2 must satisfy one of the following cases.

A. $|e_s+e_2| \cong |e_s|+|e_2|$ control period
$|e_s+e_2| \cong |e_s|+|e_2|$ gating period

B. $|e_s+e_2| \cong |e_s|+|e_2|$ control period
$|e_s+e_2| \cong |e_s|-|e_2|$ gating period

C. $|e_s+e_2| \cong |e_s|-|e_2|$ control period
$|e_s+e_2| \cong |e_s|+|e_2|$ gating period

D. $|e_s+e_2| \cong |e_s|-|e_2|$ control period
$|e_s+e_2| \cong |e_s|-|e_2|$ gating period

E. $|e_s+e_2| \cong |e_s|$ control period
$|e_s+e_2| \cong |e_s|+|e_2|$ gating period

F. $|e_s+e_2| \cong |e_s|$ control period
$|e_s+e_2| \cong |e_s|-|e_2|$ gating period

G. $|e_s+e_2| \cong |e_s|$ control period
$|e_s+e_2| \cong |e_s| \pm |e_2|$ gating period

H. $|e_s+e_2| \cong |e_s| \pm |e_2|$ control period
$|e_s+e_2| \cong |e_s| \pm |e_2|$ gating period

A plus sign or a minus sign on the right-hand side indicates that addition or subtraction always occurs regardless of the polarity of the input voltage. A plus and a minus sign indicates that either addition or subtraction may occur, depending on the input voltage polarity. These cases represent the conditions that may exist for a single basic amplifier in a magnetic amplifier consisting of an interconnection of two or four basic amplifiers.

For cases A, B, C, and D, there is output during both half periods of operation. Amplifiers with this property are obtained by parallel connecting the output ports of two basic amplifiers that gate during alternate half periods. Inasmuch as output is obtained from the basic amplifier under consideration during its gating periods, the output voltage is always subtracted from the supply voltage during the gating periods. Cases A, C, and E, therefore, do not represent practical amplifiers. When the output adds to the supply voltage during the control periods and subtracts from it during the gating periods, the output voltage is always positive because the supply voltage is an alternating voltage. The output voltage is an alternating voltage when it subtracts from the supply voltage in both control and gating periods. Thus, the output for case B is a direct voltage; and for case D it is an alternating voltage. Case F represents the well-known incomplete bridge circuit shown in Fig. 12. This amplifier circuit may be constructed by connecting two basic amplifiers of the type shown in Fig. 1(C) in series-series. Case G represents the so-called fast response, or half-cycle response, magnetic amplifier. These amplifiers are constructed by paralleling the output ports of two basic amplifiers that gate during the same half periods. Case H represents the various full-wave phase-reversible, or polarity reversible, magnetic amplifiers. These amplifiers result from connecting the output ports of four basic amplifiers in parallel.

The ideal waveform restrictions are easily satisfied for the amplifiers belonging to cases B and F. These amplifiers can be completely reset during one-half period of the supply voltage because of the large diode blocking voltage. They are inherently efficient, and may be fast or slow response amplifiers; characteristically, they give a unipolar, direct-voltage output.

The amplifiers of case D are inherently slow-response high-gain amplifiers. Speed of response may be traded for lower efficiency and lower gain, for example, by connecting resistors in series with the diodes. These resistors decrease the output voltage and thus increase the diode blocking voltage. Amplifiers of this type are characterized by a full-wave alternating output voltage.

The fast response, bipolar (or phase reversible if the output is an alternating voltage) amplifiers of case *g* are characterized by a low efficiency, which is evident from the magnitude of the sum of the supply and output voltage. This voltage sum is smaller during the control periods than during the gating periods. It is, therefore, difficult to obtain sufficient reset during the control periods to prevent the inductor from saturating during the gating periods. Because the amplifier consists of two basic amplifiers that gate during the same half periods, a time interval exists in which both inductors are saturated; a large circulating current results giving rise to a low efficiency.

The amplifiers belonging to case H have properties common to all the aforementioned amplifiers. The various combinations of properties that these amplifiers may possess are left to the imagination of the reader.

Violation of the ideal voltage-waveform restrictions not only prevent a linear analysis from being made, but also result in undesirable properties such as low effi-

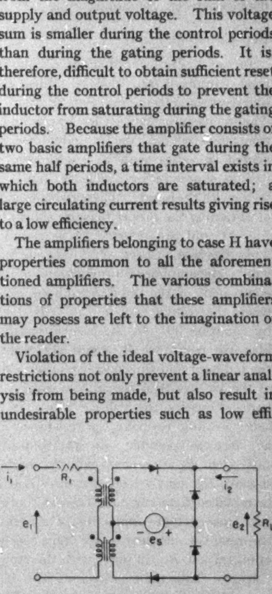


Fig. 12. Incomplete bridge circuit

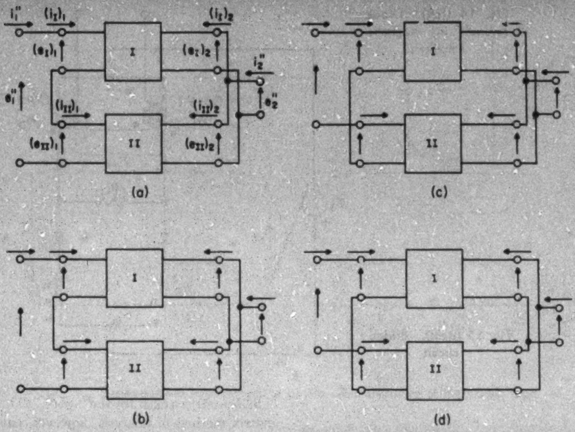

Fig. 13. The four possible subconnections for the series parallel interconnection of 2-port networks

ciency, low gain-bandwidth product, and nonlinear transfer characteristics.

Typical voltage waveforms that satisfy the ideal waveform restrictions for practical magnetic amplifiers are

1. Direct input voltage and rectangular supply voltage.
2. Alternating input voltage of the same waveform as the supply voltage.
3. Input voltage of the same waveform as half-wave or full-wave rectified supply voltage.
4. Input voltage of the same waveform as the waveform of the sum of the supply and output voltages.

NONIDEAL WAVEFORMS IN MAGNETIC AMPLIFIERS

The ideal voltage-waveform restrictions are formulated in terms of certain relations that must be satisfied among the various voltage waves. It is not logical to speak of an ideal supply, input, or output voltage, as such, because there are no restrictions imposed upon each of these voltages separately. If the supply voltage is a rectangular wave, then almost any reasonable input voltage wave will satisfy the ideal waveform restrictions. The combination of a sinusoidal supply voltage and a direct input voltage, however, does not satisfy the ideal waveform restrictions, because this combination of waveforms violates the restrictions set forth by equation 81. The amplifier nonlinearities resulting from these voltage waveforms are usually not very serious, as will be demonstrated in a later section.

The most frequently encountered input voltages which violate the ideal waveform restrictions and thus deteriorate the amplifier performance are high-frequency noise and, for amplifiers controlled by an alternating signal, quadrature signals. Both of these types of input voltages are of particular importance for the fast-response phase-reversible magnetic amplifiers. Such amplifiers are used extensively in feedback control systems in which subtractions of two large, almost equal signals are a common operation, the signal-to-noise ratio of the resultant signal being often as low as 0.01. Thus, properties such as high-frequency noise and quadrature rejection are highly desirable. Ideally, the magnetic amplifier is an average proportional amplifier; because the average value of high-frequency noise, or of random noise if the time interval in which the averaging process takes place is sufficiently long, and quadrature voltages are zero, under ideal operating conditions the magnetic amplifier should be insensitive to these input signals.

It has been shown previously that waveforms that violate the ideal-waveform restrictions tend to cause the inductor to saturate earlier in the gating period than do ideal voltage waveforms of the same half-period average values. This phenomenon causes the quiescent currents to increase in each of the basic amplifiers of which the magnetic amplifier is constructed. The quiescent currents may still cancel at the output, but the quiescent power dissipation increases, which, in turn, decreases the amplifier efficiency. This change in the quiescent operating condition with input noise is quite often a serious problem; not only does the quiescent power dissipation increase, but the amplifier may be driven to cutoff.

Interconnection of Basic Magnetic Amplifiers

In the previous section it was shown that, if the port and supply-voltage waveforms satisfy certain restrictions, the basic magnetic amplifier can be represented by a set of linear equations among average values of port voltages and currents. It was further shown that, even if these waveform restrictions are not satisfied a linear analysis can be performed in terms of incremental deviations from the quiescent condition.

This section is concerned with the analysis of magnetic amplifiers resulting from various interconnections of basic magnetic amplifiers whose port voltages and currents are linearly related.

INTERCONNECTION OF TWO BASIC AMPLIFIERS

As demonstrated in reference 1, there exist 4 different magnetic-amplifier circuits without diodes for each of the 5 basic interconnections. For magnetic amplifiers with diodes there exist 8 different circuits for each of the 5 basic interconnections. Consider, for example, subconnection *b* of the basic series-parallel interconnection of Fig. 13; the amplifier resulting is shown in Fig. 14(A). This amplifier belongs to case G of the preceding section since both inductors saturate during the same half period and the output is a half-wave polarity-reversible voltage. Suppose, now, that the diode of basic amplifier *II*, as seen in Fig. 13, is reversed. The resultant circuit is shown in Fig. 14(B), and it belongs to case B; the inductors saturate during alternate half periods and the output is a positive direct voltage. Thus, for each of the subconnections of Fig. 13, there exist 2 different circuits: one is obtained by connecting the ports of 2 ordinary basic amplifiers according to the particular subconnection and the other by reversing either one of the diodes in this circuit. It is beyond the scope of this work to consider all of the possible interconnections of 2 basic amplifiers; it must suffice to say that there exists a total of 40 different circuits inasmuch as there are 5 basic interconnections comprising 8 subconnections each. Not all of these interconnections result in practical amplifiers; for example, the circuits resulting from series connecting the output ports are impractical. However, by connecting a diode across the output port

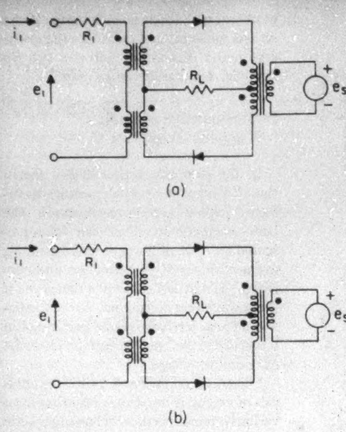

Fig. 14 (left). Diode reversal in magnetic amplifiers

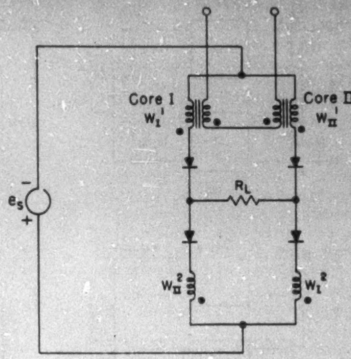

Fig. 15 (right). Bridge circuit

of each basic amplifier, some of the impractical interconnectious may become practical amplifiers. An example of such an amplifier is shown in Fig. 12.

Another group of magnetic amplifiers not considered in the foregoing are the bridge circuits, of which Fig. 15 is an example. Apparently, the bridge circuits cannot be constructed by an interconnection of basic amplifiers. This apparent difficulty can be overcome by splitting the gate winding into two equal parts and by adding another diode in series with the one already in the circuit. The resulting basic magnetic amplifier is shown in Fig. 16. Evidently, the circuit equations of this new basic amplifier are identical to those of the original basic amplifier, since series addition of gate windings and diodes and an interchange in the order of elements connected in series do not effect the operation of the basic amplifier. In Fig. 16 two of these basic amplifiers are connected in series-parallel. The voltage drops between x and x', and y and y' are given by the equations

$$e_{xx}'=e_s-e_x-e_y' \tag{82}$$

$$e_{yy}'=e_s-e_x-e_y' \tag{83}$$

The voltages e_x and e_y, and e_x' and e_y' are equal. Writing Kirchoff's loop equation around the main loop yields

$$2e_s-2e_x-2e_x'=0 \tag{84}$$

or

$$e_x+e_x'=e_s \tag{85}$$

Thus, equations 82 and 83 become

$$e_{xx}'=0$$

$$e_{yy}'=0 \tag{86}$$

The points x and x', and y and y', therefore, can be joined without disturbing the operation of the amplifier; the magnetic-amplifier circuit of Fig. 15 results.

Quite often a resistance is connected in series with the supply source to limit the supply current when both inductors are saturated simultaneously and to improve the amplifier performance. Thus, the voltage across the terminals x and y, and x' and y' depend upon the voltages and currents at the ports. To take into account this effect, the basic amplifier is viewed as a 3-port network, the supply-voltage terminals being the third port. The matrix method of analysis is still applicable since no potential difference exists between the terminals to be joined, as shown by equation 86. In the following subsection the matrix method of determining the behavior of interconnected 2-port networks will be extended to n-port networks.

INTERCONNECTION OF NETWORKS WITH n PORTS

The analysis of interconnected basic amplifiers reduces to simple matrix addition or multiplication if the proper relationships among the port voltages and currents are used. These relations are not so evident for an interconnection of n-port networks as for 2-port networks, because only the Y and Z matrices* exist for the n-port while the $Y,Z,H,G,$ and $ABCD$ matrices exist for the 2-port. The matrix method of analysis, however, can easily be extended to interconnections of networks with an arbitrary number of ports. Any two n-port networks where all the ports are connected pair-wise in series or parallel can be analyzed easily by using the impedance or the admittance matrix relations. It is also evident that a series, or parallel, interconnection of an arbitrary number, m, of n-port networks can be analyzed in the same manner. A series, or parallel, interconnection is obtained when one port from each of the m networks is connected in series, or parallel, with all other $m-1$ like ports and so forth for the remainder of the n ports.

Consider now the case in which ports 1 of all the m networks are connected in series, ports 2 of all the m networks connected in parallel, and so on in a random fashion. The ports can be renumbered so that the port numbers for the series-connected ports run from 1 to p, and from $p+1$ to n for the parallel-connected ports. If the matrix of the interconnected network is to be the sum of the individual network matrices, then all the port quantities that are summed, voltages for series connections and currents for parallel connections, must appear on the left-hand side of the matrix equation or must be chosen as the dependent variables. The port quantities that remain invariant during the interconnections, voltages for parallel connections and currents for series connections, must appear on the right-hand side of the equation or must be chosen as the independent variables. Thus, the proper relationship among the port variables of each network for the interconnection in question is shown by equation 87 where M is an m-by-m matrix.

---

* The scattering matrix and its inverse, the gathering matrix, also exist for an n-port network. To limit the scope of the analysis these matrix relations have been omitted. The usefulness of the scattering matrix in the analysis of magnetic amplifiers have been demonstrated in unpublished notes by G. T. Coate of the Servomechanisms Laboratory at Massachusetts Institute of Technology.

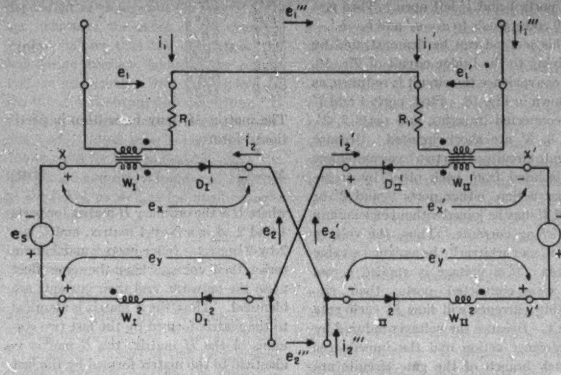

Fig. 16. Series parallel interconnection of two basic amplifiers of the bridge type

$$\left\|\begin{matrix} e_1 \\ e_2 \\ \cdot \\ \cdot \\ e_p \\ i_{p+1} \\ i_{p+2} \\ \cdot \\ \cdot \\ i_n \end{matrix}\right\| = M \left\|\begin{matrix} i \\ i_2 \\ \cdot \\ \cdot \\ i_p \\ e_{p+1} \\ e_{p+2} \\ \cdot \\ \cdot \\ e_n \end{matrix}\right\| \qquad (87)$$

Similar relations can be written for all the other $m-1$ networks. If for network I the following notation is used,

$$\alpha_I = \left\|\begin{matrix} (e_I)_1 \\ \cdot \\ \cdot \\ (e_I)_p \\ (i_I)_{n+1} \\ \cdot \\ \cdot \\ (i_I)_n \end{matrix}\right\| ; \beta_I = \left\|\begin{matrix} (i_I)_1 \\ \cdot \\ \cdot \\ (i_I)_p \\ (e_I)_{n+1} \\ \cdot \\ \cdot \\ (e_I)_n \end{matrix}\right\| \qquad (88)$$

then equation 87 can be written

$$\alpha_I = M_I\beta_I \qquad (89A)$$

Similarly, for the other $m-1$ networks

$$\alpha_{II} = M_{II}\beta_{II}$$

$$\cdot \quad \cdot$$

$$\cdot \quad \cdot$$

$$\alpha_M = M_M\beta_M \qquad (89B)$$

Because ports 1 through p are connected in series and ports $p+1$ through n are connected in parallel, the port voltages and currents of the interconnected network are related to the port voltages and currents of the individual networks by the equations:

$$\left.\begin{matrix} e_k = \sum_{j=I}^{M} (e_j)_k \\ i_k = \sum_{j=I}^{M} (e_j)_k \end{matrix}\right\} \text{for } k=1, 2, \ldots, p \qquad (90)$$

$$\left.\begin{matrix} e_k = (e_j)_k \\ e_k = (i_j)_k \end{matrix}\right\} \begin{matrix}\text{for } j=I, II, \ldots, M \\ \text{and } k=p+1, p+2, \ldots, n\end{matrix} \qquad (91)$$

It is tacitly assumed that the polarities of the port voltages and currents of equations 8(A) and (B) are chosen so that no polarity reversal occurs during the interconnection. Thus, if the matrix equations for the individual networks are added, the matrix equation for the final interconnection is obtained as follows:

$$\alpha = (M_I + M_{II} + \ldots + M_M)\beta \qquad (92)$$

Practical magnetic amplifiers consist of interconnections of identical basic amplifiers. The matrix for these amplifiers, therefore, can be written in the form

$$M = M_I + T_{II}M_IT_{II} + \ldots + T_MM_IT_M \qquad (93)$$

where the T's are the transformation matrices. These matrices account for polarity changes in the port quantities and interchanges of control and gating periods that may occur through interconnections.

For networks constructed from more than two basic elements, or basic amplifiers, there exist other types of interconnections than those considered in the foregoing. A typical example of such an interconnection is the 3-phase amplifier analyzed in reference 1. This amplifier was obtained by connecting two basic elements in series-series and then connecting three of these series-series interconnections in parallel-parallel. A large number of such interconnections exists. Usually, these interconnections can be divided into groups of interconnections, the first group being the interconnection of basic elements to form a number of identical amplifiers. These new amplifiers may then be considered elements for the next group of interconnections, and so forth. The analysis is performed by first determining the relations among port voltages and currents of the first group. Then these relations are used to obtain rela-

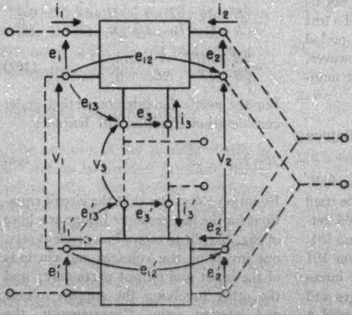

Fig. 17. Validity test for matrix method of determining composite behavior for 3-port networks

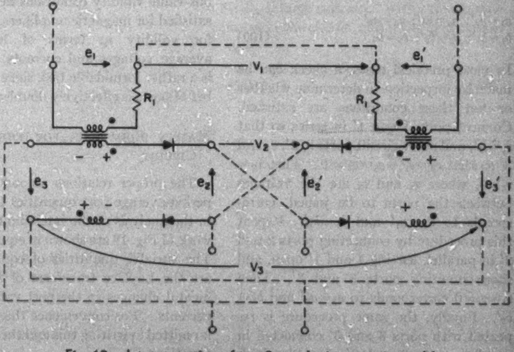

Fig. 18. Interconnection of two 3-port basic magnetic amplifiers

tions among port voltages and currents of the second group, and so forth. Because these groups of amplifiers are formed by different types of interconnections, the relations among port quantities obtained for one group must be rewritten to the form desired for the next group of interconnections in order to apply the matrix method of analysis. This step in the analysis may be involved because matrix inversion of 4-by-4 matrices or larger may be required.

VALIDITY TESTS FOR MATRIX METHOD OF ANALYSIS

The tests that must be performed on a network to insure the validity of the matrix method of determining the composite behavior of interconnected subnetworks are described by Guillemin for ordinary 2-port networks.[2] These same tests can be generalized for the interconnection of n-port networks. For the purpose of illustration, the test procedure for 3-port networks is developed here. Consider the series-parallel-parallel interconnection of Fig. 17, and suppose for the network N that

$$e_{12}=a_1i_1+a_2e_2+a_3e_3 \tag{94}$$

$$e_{13}=b_1i_1+b_2e_2+b_3e_3 \tag{95}$$

and for the network N' that

$$e_{12}'=a_1'i_1'+a_2'e_2'+a_3'e_3' \tag{96}$$

$$e_{13}'=b_1'i_1'+b_2'e_2'+b_3'e_3' \tag{97}$$

For no circulating currents to flow the conditions

$$e_{12}=e_{12}';\ e_{13}=e_{13}' \tag{98}$$

subject to the restrictions that

$$i_1=i_1';\ e_2=e_2';\ e_3=e_3' \tag{99}$$

must be satisfied for all values of i_1, e_2, and e_3. These conditions are satisfied if

$$\begin{aligned}&a_1=a_1';\ a_2=a_2';\ a_3=a_3'\\&b_1=b_1';\ b_2=b_2';\ b_3=b_3\end{aligned} \tag{100}$$

In most practical cases, a check can be made by inspection to determine whether or not these conditions are satisfied. Connect ports 1 and 1′ in series so that $i_1=i_1'$, and short-circuit ports 2, 2′, 3, and 3′ so that $e_2=e_2'=e_3=e_3'=0$. Then $v_2=v_3=0$, where v_2 and v_3 are the voltages between the ports to be joined, corresponds to $a_1=a_1'$ and $b_1=b_1'$. Repeat this procedure by connecting ports 2 and 2′ in parallel, leaving 1 and 1′ open, and short-circuiting ports 3 and 3′. Then $v_1=v_3=0$ corresponds to $a_2=a_2'$ and $b_2=b_2'$. Finally, the same procedure is repeated with ports 3 and 3′ connected in parallel, ports 2 and 2′ short-circuited, and ports 1 and 1′ left open. Then $v_1=v_2=0$ corresponds to $a_3=a_3'$ and $b_3=b_3'$.

This method can be demonstrated by applying to the bridge circuit of Fig. 16. For convenience the circuit is redrawn, as is shown in Fig. 18. First, ports 1 and 1′ are connected in series, and ports 2, 2′, and 3, 3′ are short-circuited. Because the gate circuits of the two basic amplifiers are isolated from each other by transformer action, either ports 2 and 2′ or 3 and 3′ may be joined without causing any circulating currents. Thus, the voltage v_2, or v_3, can arbitrarily be assigned a value of zero. If a voltage is applied across the series-connected ports, then circulating currents will flow in each gate circuit. Because the voltages induced by transformer action and the impedances in each branch of the gate circuits are respectively equal, the voltage v_3 must be zero. In the next step, ports 2 and 2′ are connected in parallel, ports 1 and 1′ are left open, and ports 3 and 3′ are short-circuited. By inspection, v_1 is zero; and from symmetry consideration, v_3 must also be zero. The third test is identical to the one just mentioned since there exists complete symmetry between ports 2 and 2′, and 3 and 3′. Thus, it has been shown that the matrix method of determining the composite behavior is valid for this particular interconnection. It is further evident that any series-parallel-parallel interconnection of basic 3-port bridge elements satisfies the validity tests.

For magnetic amplifiers the validity conditions need only be satisfied for half-period average voltages and currents. If the validity conditions are satisfied at any instant, as in the case of the bridge circuit discussed in the foregoing, then it follows that they also are satisfied for half-period average voltages and currents. It should be pointed out that the instantaneous-value validity conditions need not be satisfied for magnetic amplifiers. To test for validity in terms of half-period average voltages and currents, however, is a rather formidable task since the number of ports is effectively doubled.

MATRIX EQUATIONS FOR THE BRIDGE CIRCUIT

The proper relations among the half-period average port quantities to be used in the analysis of the interconnected network of Fig. 18 are shown in equation 101. The variable quantities of equation 101 are the Laplace transform of the incremental changes in the port voltages and currents. For convenience the symbol Δ is omitted in writing this and the following equations.

$$\begin{Vmatrix}E_1^c\\E_1^g\\I_2^c\\I_2^g\\I_3^c\\I_3^g\end{Vmatrix}=M_I\begin{Vmatrix}I_1^c\\I_1^g\\E_2^c\\E_2^g\\E_3^c\\E_3^g\end{Vmatrix} \tag{101}$$

The matrix M_I may be written in partitioned form

$$M_I=\begin{Vmatrix}H & A\\B & C\end{Vmatrix} \tag{102}$$

where H is the ordinary H matrix for ports 1 and 2, A is a 2-by-4 matrix, and C is a 2-by-2 matrix. Since ports 2 and 3 are in series, their voltages have the same effect upon the network, and their currents are identical. Thus, the A matrix is identical to the matrix formed by the last two columns of the H matrix, the B matrix is identical to the matrix formed by the last two rows, and the C matrix is identical to the h_{22} submatrix.

$$A=\begin{Vmatrix}h_{12}^{cc} & h_{12}^{cg}\\h_{12}^{gc} & h_{12}^{gg}\\h_{22}^{cc} & h_{22}^{cg}\\h_{22}^{gc} & h_{22}^{gg}\end{Vmatrix}=\begin{Vmatrix}h_{12}\\h_{22}\end{Vmatrix} \tag{103}$$

$$B=\begin{Vmatrix}h_{21}^{cc} & h_{21}^{cg} & h_{22}^{cc} & h_{22}^{cg}\\h_{21}^{gc} & h_{21}^{gg} & h_{22}^{gc} & h_{22}^{gg}\end{Vmatrix}=\begin{Vmatrix}h_{21} & h_{22}\end{Vmatrix} \tag{104}$$

$$C=\begin{Vmatrix}h_{22}^{cc} & h_{22}^{cg}\\h_{22}^{gc} & h_{22}^{gg}\end{Vmatrix}=h_{22} \tag{105}$$

The transformation matrix is obtained by inspection and is

$$T'=\begin{Vmatrix}-1 & 0 & 0 & 0 & 0 & 0\\0 & -1 & 0 & 0 & 0 & 0\\0 & 0 & -1 & 0 & 0 & 0\\0 & 0 & 0 & -1 & 0 & 0\\0 & 0 & 0 & 0 & 1 & 0\\0 & 0 & 0 & 0 & 0 & 1\end{Vmatrix}=\begin{Vmatrix}T & 0\\0 & U\end{Vmatrix} \tag{106}$$

where the matrix T is the ordinary 4-by-4 transformation matrix. In general, the matrix of a series-parallel-parallel interconnection of two basic 3-port amplifiers becomes

$$\begin{aligned}M&=M_I+T'M_IT'\\&=\begin{Vmatrix}H & A\\B & C\end{Vmatrix}+\begin{Vmatrix}T & 0\\0 & U\end{Vmatrix}\begin{Vmatrix}H & A\\B & C\end{Vmatrix}\begin{Vmatrix}T & 0\\C & U\end{Vmatrix}\\&=\begin{Vmatrix}H+THT & A+TA\\B+BT & 2C\end{Vmatrix}\end{aligned} \tag{107}$$

For the particular interconnection under consideration equation 107 becomes

$$M=2\begin{Vmatrix}H & 0\\0 & C\end{Vmatrix} \tag{108}$$

Equation 108 shows that the circuit equations for the fast-response bridge amplifier of Fig. 15 split into two independent sets: one involving the voltages and currents of the input and output ports only; and the other involving the supply voltage and current only. Consequently, the half-period average currents and voltages at the input and output ports are independent of changes in the supply voltage, whatever the cause of the changes. It also follows that the changes in the half-period average values of the supply voltage and current are independent of the input and output port quantities. If the ideal waveform restrictions are satisfied and if ideal bias is used, equation 108 is valid for the actual values of the half period average voltages and currents at the ports, as well as for small changes in port quantities.

INTERCONNECTION OF FOUR BASIC MAGNETIC AMPLIFIERS

For the purpose of analysis, a 4-core magnetic amplifier may be viewed as an interconnection of four basic amplifiers. All practical circuits of this type possess complete symmetry so that the number of useful amplifiers is small compared to the number of possible interconnections. No particular new features of interest are introduced by these circuits, and they can be analyzed in the manner already described in the foregoing.

CONCLUSION

The matrix method of analysis discussed in this section is, to the author's knowledge, applicable to all known single-phase magnetic amplifiers. Although this method of analysis may not be the shortest one for a particular circuit, it provides a general means of analysis and gives a clearer insight to the over-all properties of magnetic amplifiers.

Quite often additional control windings are provided for summing purposes. The effect of such additional windings on the amplifier performance can readily be determined by the use of superposition. Feedback is often used to improve the amplifier linearity; its effect upon the amplifier can be analyzed by conventional feedback techniques.

To demonstrate the method of analysis developed, the well-known doubler circuit shown in Fig. 19 will be analyzed in the following section.

Analysis of Doubler Circuit

The analysis of the doubler circuit in this section is divided into two parts: analysis with ideal voltage waveforms, and analysis with nonideal voltage waveforms. Since this analysis is made for the explicit purpose of demonstrating the important ideas developed in this work, the latter part of the analysis is limited to input signal variations for which sequence of transitions *c* occurs. As a result, only part of the amplifier transfer characteristic when resistively loaded is derived.

The doubler circuit may be constructed by connecting two basic amplifiers in series-parallel as shown in Fig. 20. To obtain the proper circuit configuration, it is necessary to reverse the polarity of the supply voltage and the voltage and current at port 2 of basic amplifier *II*. As shown in reference 1 reversal of the supply-voltage polarity may cause the inductors to saturate during alternate half periods. Inspection of the circuit in Fig. 19 indeed shows that the inductors saturate during alternate half periods.

To apply the matrix method of determining the composite behavior, the basic amplifiers must be represented analytically by the H matrix. The H matrix relating incremental signal quantities for the interconnection is of the form

$$H=H_I+TH_{II}T \qquad (109)$$

where H_I and H_{II} are the matrices of the basic amplifiers and T the transformation matrix. The matrix T is obtained by inspection and is

$$T=\begin{Vmatrix}0 & 1 & 0 & 0\\ 1 & 0 & 0 & 0\\ 0 & 0 & 0 & -1\\ 0 & 0 & -1 & 0\end{Vmatrix} \qquad (110)$$

IDEAL VOLTAGE WAVEFORMS

The H matrices of the two basic amplifiers are identical and are given by equation 111

$$H_I=\begin{Vmatrix}R_1'+R_3 & 0 & \dfrac{R_3}{R_b} & 0\\ -R_3\dfrac{1}{z} & R_1' & -\dfrac{R_3}{R_b}\dfrac{1}{z} & 0\\ -\dfrac{R_3}{R_b} & 0 & \dfrac{R_3}{R_mR_b} & 0\\ \dfrac{R_3}{R_f}\dfrac{1}{z} & 0 & \dfrac{R_3}{R_fR_b}\dfrac{1}{z} & \dfrac{1}{R_f}\end{Vmatrix} \qquad (111)$$

where

$$R_1'=\frac{1}{2}R_1 \qquad (112)$$

$$R_3=\frac{R_mR_b}{R_m+R_b} \qquad (113)$$

Substitution of equations 110, 111, and 112 in equation 109 yields

$$H=\begin{Vmatrix}R_1+R_3 & -R_3\dfrac{1}{z} & (-)\dfrac{R_3}{R_b} & \dfrac{R_3}{R_b}\dfrac{1}{z}\\ -R_3\dfrac{1}{z} & R_1+R_3 & \underline{(+)}\dfrac{R_3}{R_b}\dfrac{1}{z} & -\dfrac{R_3}{R_b}\\ \underline{(+)}\dfrac{R_3}{R_b} & \underline{(+)}\dfrac{R_3}{R_b}\dfrac{1}{z} & \dfrac{R_3}{R_mR_b}+\dfrac{1}{R_f} & (-)\dfrac{R_3}{R_fR_b}\dfrac{1}{z}\\ \dfrac{R_3}{R_f}\dfrac{1}{z} & \dfrac{R_3}{R_b} & (-)\dfrac{R_3}{R_fR_b}\dfrac{1}{z} & \dfrac{R_3}{R_mR_b}+\dfrac{1}{R_f}\end{Vmatrix} \qquad (114)$$

Because the output of the doubler circuit is an alternating voltage when the input is a direct voltage, the matrix of equation 114 exhibits the same symmetry property as discussed in reference 1 for the series-connected saturable inductor. Reversal of the polarity of the output voltage and current during every other half period corresponds to pre- and post-multiplying the matrix H by the matrix

$$A=\begin{Vmatrix}1 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & -1 & 0\\ 0 & 0 & 0 & 1\end{Vmatrix} \qquad (115)$$

This operation changes the sign of the matrix elements as indicated in parentheses in equation 114. Using these signs, addition of the first two rows and the last two rows yields

$$E_1=\left\|R_1+R_3\left(1-\frac{1}{z}\right)\right\|I_1-\frac{R_3}{R_b}\left(1-\frac{1}{z}\right)E_2 \qquad (116)$$

$$I_2=\left(\frac{R_3}{R_b}+\frac{R_3}{R_f}\frac{1}{z}\right)I_1+\left\|\frac{1}{R_f}+\frac{R_3}{R_mR_b}-\frac{R_3}{R_fR_b}\frac{1}{z}\right\|E_2 \qquad (117)$$

To obtain the transfer characteristic with resistive load, the following additional equation is needed.

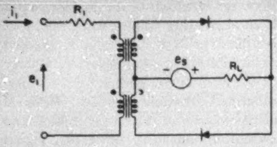
$$E_2=-R_LI_2 \qquad (118)$$

Eliminating I_1 and I_2 from equations 116, 117, and 118 and solving for the ratio E_2/E_1 yield the expression

$$\frac{E_2}{E_1}=-\frac{R_mR_L\left(R_f+R_b\dfrac{1}{z}\right)}{(R_f+R_L)(R_mR_1+R_bR_1+R_mR_b)+(R_1+R_m)R_fR_L-(R_f+R_L)R_mR_b+(R_f+R_1)R_mR_L\dfrac{1}{z}} \qquad (119)$$

If R_m is large compared with other resistances in the circuit, and if the approximation

$$z\cong 1+\frac{\pi}{\omega}s \qquad (120)$$



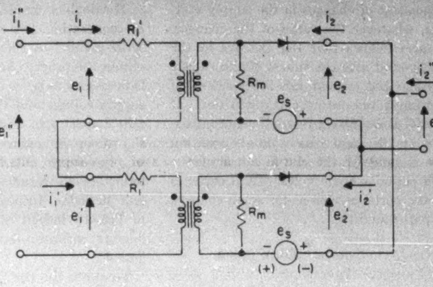


Fig. 19 (left). Doubler circuit

Fig. 20 (right). Doubler circuit as an interconnection of two basic amplifiers

is made, then the following approximate transfer function is obtained.

$$\frac{\bar{E}_2}{\bar{E}_1} \cong -\frac{R_L(R_f+R_b)}{R_fR_1} \times \frac{\dfrac{R_f}{R_f+R_b}\dfrac{\pi}{\omega}s+1}{\left\|\left(1+\dfrac{R_L}{R_f}\right)\left(1+\dfrac{R_b}{R_1}\right)+\dfrac{R_L}{R_1}\right\|\dfrac{\pi}{\omega}s+1} \tag{121}$$

The transfer function of equation 121 can be further simplified by making use of the inequalities: $R_b >> R_f$ and $R_1 >> R_L$ (the latter is not always satisfied).

$$\frac{\bar{E}_2}{\bar{E}_1} \cong -\frac{R_LR_b}{R_fR_1}\frac{1}{\left(1+\dfrac{R_L}{R_f}\right)\left(1+\dfrac{R_b}{R_1}\right)\dfrac{\pi}{\omega}s+1} \tag{122}$$

The transfer function of equation 122 is identical to the one previously derived by the author.[3] A word of caution is necessary in regard to the derivation of equation 122. Equation 122 was obtained, among others, by letting $R_m \to \infty$; this limiting process is not valid if the saturable-inductor loop width is small. In Appendix II it is shown that for the limiting case when $R_m >> R_b$ and the loop width is zero, the diodes conduct during part of the control and block during part of the gating periods of their respective inductors. Bourne and Nitzen have shown that this phenomenon very rarely occurs in practical magnetic amplifiers because of the finite loop-width property of the saturable inductors.[4] In Appendix II it is further shown that the magnetizing resistance alone usually prevents this phenomenon from occurring.

Since the advent of silicon diodes, diode back impedances have become considerably greater than the magnetizing impedance; the inequalities $R_b >> R_f$ and $R_b >> R_m$ then apply so that the transfer function of equation 119 can be written as follows:

$$\frac{\bar{E}_2}{\bar{E}_1} \cong -\frac{R_mR_L}{(R_f+R_L)R_1}\frac{1}{\dfrac{R_1+R_m}{R_1}\dfrac{\pi}{\omega}s+1} \tag{123}$$

Another interesting relation can be obtained from equation 121. Suppose the two diodes in the doubler circuit are short-circuited, then the familiar series-parallel interconnection of two basic elements, basic amplifiers without diodes, results. The approximation that R_m is large compared to the other resistances in the circuit is now valid, and the transfer function of this new amplifier is obtained by substituting $R_f = R_b = R_2$ in equation 121.

$$\frac{\bar{E}_2}{\bar{E}_1} = -\frac{2R_L}{R_1}\frac{\dfrac{\pi}{\omega}s+1}{\left\|\left(1+\dfrac{R_L}{R_2}\right)\left(1+\dfrac{R_2}{R_1}\right)+\dfrac{R_L}{R_1}\right\|\dfrac{\omega}{\pi}s+1} \tag{124}$$

The transfer function derived relates changes in the input and output voltages from their quiescent values. If ideal bias is used, then the steady-state transfer characteristic can be obtained by making the substitution

$z \to 1$

$\bar{E}_1 \to E_1,\ \bar{E}_1 \to I_1,\ I_2 \to I_2$

$\bar{E}_2 \to E_2 + E_s'$

in equations 116 and 117. By making use of the relation $E_2 = -R_LI_2$ and eliminating I_1 and I_2 from the resulting equations, the following expression is obtained:

$$\left\|\frac{1}{R_f}+\frac{1}{R_L}+\frac{R_3}{R_b}\left(\frac{1}{R_m}-\frac{1}{R_f}\right)\right\|E_2 = -\frac{R_3}{R_f}\left(\frac{1}{R_b}+\frac{1}{R_f}\right)E_1 - \left\|\frac{1}{R_f}+\frac{R_3}{R_b}\left(\frac{1}{R_m}-\frac{1}{R_f}\right)\right\|E_s' \tag{125}$$

The voltage E_s' in equation 125 is related to the supply voltage through a transformation similar to the one used in reducing the four by four matrix of equation 114 to a 2-by-2 matrix. This transformation reversed the polarity of the output voltage during the control periods of basic amplifier *1*. From this transformation and because the supply voltage is positive during the control periods and negative during the gating periods, it is seen that the voltage E_s' in equation 125 is always negative. Making use of this property and solving equation 125 for E_2 yields

$$E_2 = \frac{R_L(R_b+R_f)}{R_f(R_m+R_L)+R_b(R_f+R_L)} \times \left\|-\frac{R_m}{R_1}E_1+|E_s|\right\| \tag{126}$$

To compare the results of this and the following subsections, a special case will be considered in which the resistance values and the loop width are related by the equations:

$R_L = R_f = 0.001R$

$R_m = R_b = R$

$R_1 = 0.1R$

$$I_c = \frac{|E_s|}{2R} \tag{127}$$

Substitution of equation 127 in equation 126 gives

$$E_2 = 3.33E_1 + 0.333|E_s| \tag{128}$$

Since $R_L = R_f$, the maximum output is $0.5|E_s|$. The steady-state transfer characteristic is plotted in Fig. 21. The solid line represents the condition of ideal bias, and the dashed line represents the condition of no bias. The two curves are shifted horizontally an amount $R_1I_c = 0.05|E_s|$ from each other.

SINUSOIDAL SUPPLY VOLTAGE AND DIRECT INPUT VOLTAGE

In order to apply the method of analysis developed in the foregoing sections, the voltage waveforms that exist at the input and output ports of each basic amplifier must be known. Because of symmetry these voltage waveforms are the same for both basic amplifiers of which the doubler circuit is constructed. The input ports of the two basic amplifiers are connected in series as shown in Fig. 20. Thus, the voltage that exists across the input ports of each basic amplifier is the sum of the input voltage applied to the doubler circuit and the voltage that exists across the inductor of the other basic amplifier. In Appendix II it is shown that the waveform approximations apply for this case, and that the constant terms in the expressions for the waveform approximations are:

For t near zero,

$$\frac{E_s}{T_s}=\frac{\pi^2}{T}E_s,\ \frac{E_2}{T_2}=0,\ \frac{E_1}{T_1}=\frac{\pi^2}{T'}E_s$$

$$E_1'=E_1 \qquad (129)$$

For t near $T/2$,

$$\frac{E_s}{T_s}=\frac{\pi^2}{T}E_s,\ \frac{E_2}{T_2}=\frac{R_L}{R_L+R_f}\frac{\pi^2}{T}E_s,\ \frac{E_1}{T_1}=0$$

$$E_1''=E_1 \qquad (130)$$

These waveform approximations are valid for sequence of transitions c only. If the direct input voltage is greater than R_1I_c, sequence of transitions b occurs; if it is less than R_1I_c, sequence of transitions c occurs. To limit the analysis to a reasonable length, only sequence of transitions c is considered; and as a result only part of the steady-state transfer characteristic is derived.

The circuit equations for sequence of transitions c are derived in Appendix II. Substituting equations 129 and 130 in equation 162 yields

$$E_R{}^c=c(E_1{}^c-R_1I_c)+d(E_s{}^c+E_2{}^c)+ c\left\|\frac{R_b}{R_1}\frac{R_L+R_f}{R_f}+\frac{R_bR_1}{R_1(R_1+R_b)}\right\|\times \frac{1}{\pi^2E_s}(E_1-R_1I_c)^2 \qquad (131)$$

where E_1 is the input voltage to the doubler circuit. Equation 131, together with equations 44 through 48, determine the steady-state characteristic of the amplifier. Since these equations are nonlinear, the matrix method of determining the composite behavior is not applicable. However, since these equations are valid for any operating point as long as sequence of transitions c occurs, the slope of the steady-state transfer characteristic can be determined by small signal analysis. The matrix method of determining the composite behavior is then applicable since equation 131 can be linearized around any operating point. In terms of incremental signal quantities equation 131 becomes

$$\delta E_R{}^c=c\delta E_1{}^c+d\delta E_2{}^c+cq\delta E_1' \qquad (132)$$

where

$$q=\left\|\frac{R_b}{R_1}\frac{R_L+R_f}{R_f}+\frac{R_bR_1}{R_1(R_1+R_b)}\right\|\times \frac{2}{\pi^2E_s}(E_1-R_1I_c) \qquad (133)$$

and δ is the differential operator.

The term $\delta E_1'$ in equation 132 is the change in the average input voltage to the doubler circuit that occurs during the control periods of basic amplifier I. Thus, $\delta E_1'$ is zero during the gating periods of basic amplifier I. $\delta E_1'$ should not be confused with $\delta E_1{}^c$ which is the change in the average voltage at the input port of amplifier I during the control periods. This latter quantity is the sum of $\delta E_1'$ and the change in the average voltage that appears across the control winding of basic amplifier II during its gating periods. Since the voltages $E_1{}^c$, and $E_1{}^g$, and E_1' can be adjusted independently of each other, these voltages can be considered independent variables.

In terms of increment signal quantities equations 44 through 48 become:

$$\delta E_1{}^c=R_1\delta I_1{}^c+\delta E_R{}^c \qquad (134)$$

$$\delta E_2{}^c=R_b\delta I_2{}^c+\delta E_R{}^c \qquad (135)$$

$$\delta E_1{}^g=R_1\delta I_1{}^g+\delta E_R{}^g \qquad (136)$$

$$\delta E_2{}^g=R_f\delta I_2{}^g+\delta E_R{}^g \qquad (137)$$

$$\delta E_R{}^c+\delta E_R{}^g=0 \qquad (138)$$

From these equations and equation 132 the H matrix of basic amplifier I can be obtained. Since these equations are identical to the equations obtained for the linear case, except for the term $cq\delta E_1'$ in equation 132, the matrix equation of basic amplifier I becomes:

$$\alpha_I=H_I\beta_I+P\delta E_I' \qquad (139)$$

where P is the matrix

$$P=q\left\|\begin{matrix}\frac{c}{1-c}\\ -\frac{c}{1-c}\\ -\frac{c}{1-c}\frac{1}{R_b}\\ \frac{c}{1-c}\frac{1}{R_f}\end{matrix}\right\| \qquad (140)$$

and H_I is obtained by substituting $z=1$ in equation 111. Similarly, for basic amplifier II

$$\alpha_{II}=H_I\beta_{II}+P\delta E_1'' \qquad (141)$$

where $\delta E_1''$ is the change in the half-period average value of the input voltage to the doubler circuit during the control periods of basic amplifier II. Performing the transformation of variables indicated by the equation

$$\alpha_{II}=T\alpha_{II}'$$

$$\beta_{II}=T\beta_{II}' \qquad (142)$$

yields

$$\alpha_{II}'=TH_IT\beta_{II}'+TP\delta E_I'' \qquad (143)$$

To obtain the matrix of the series-parallel interconnected amplifier, equations 139 and 143 are added.

$$\alpha_I+\alpha_{II}'=H_I\beta_I+TH_IT\beta_{II}'+ P\delta E_1'+TP\delta E_1'' \qquad (144)$$

But, since

$$\alpha_I+\alpha_{II}'=\alpha$$

$$\beta_I=\beta_{II}'=\beta \qquad (145)$$

where α and β are the variables of the interconnected amplifier, equation 144 can be rewritten

$$\alpha=\|H_I+TH_IT\|\beta+P\delta E_1'+TP\delta E_1'' \qquad (146)$$

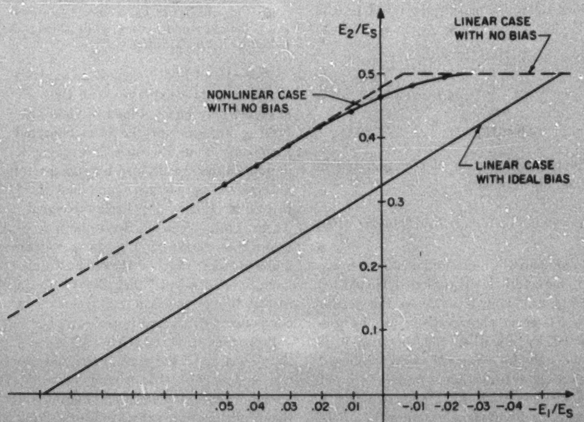

Fig. 21. Steady-state transfer characteristics

The last two terms in equation 146 can be written alternatively:

$$P\delta E_1'+TP\delta E_1''=$$

$$q\left\|\begin{matrix}\frac{c}{1-c} & -\frac{c}{1-c}\\ -\frac{c}{1-c} & \frac{c}{1-c}\\ \underline{(+)}\frac{c}{1-c}\frac{1}{R_b} & \underline{(+)}\frac{c}{1-c}\frac{1}{R_f}\\ \frac{c}{1-c}\frac{1}{R_f} & \frac{c}{1-c}\frac{1}{R_b}\end{matrix}\right\|\left\|\begin{matrix}\delta E_1'\\ \delta E_1''\end{matrix}\right\|$$

$$=qRS \qquad (147)$$

when R and S are the matrices indicated. Ignore, for the time being, the signs in parentheses in equation 147. Again the number of variables can be reduced by making use of the transformation of variables expressed by the matrix of equation 115. Thus, let

$$\alpha=A\alpha' \qquad (148)$$

$$\beta=A\beta'$$

Substitution of equations 147 and 148 in equation 146 yields

$$\alpha'=A\|H_I+TH_IT\|A\beta'+qARS \qquad (149)$$

Premultiplying the matrix R by the matrix A changes the signs in R as indicated in parentheses in equation 147. Addition of the first two rows and the last two rows of the matrix equation, equation 149, yield

$$\delta E_1=R_1\delta I_1 \qquad (150)$$

$$\delta I_2=R_3\left(\frac{1}{R_b}+\frac{1}{R_f}\right)\delta I_1+\left\|\frac{1}{R_f}+\frac{R_3}{R_b}\left(\frac{1}{R_m}-\frac{1}{R_f}\right)\right\|\delta E_2+\frac{2R_3}{R_1}\left(\frac{1}{R_b}+\frac{1}{R_f}\right)q(\delta E_1'+\delta E_1'') \qquad (151)$$

From the definitions of $\delta E_1'$ and $\delta E_1''$, it is seen that

$$\delta E_1'+\delta E_1''=\delta E_1 \qquad (152)$$

To determine the steady-state transfer characteristic with resistive load, equation 152 and the relation $\delta E_2=-R_L\delta I_2$ are substituted in equation 151. Then by using equation 150 to eliminate δI_1, the following differential equation is obtained.

$$\left\|\frac{1}{R_f}+\frac{1}{R_L}+\frac{R_3}{R_b}\left(\frac{1}{R_m}-\frac{1}{R_f}\right)\right\|\delta E_2=-\left(\frac{1}{R_b}+\frac{1}{R_f}\right)\frac{R_3}{R_1}(1+2q)\delta E_1 \qquad (153)$$

The quantity q, as seen from equation 133, is a function of E_1 and may be written in the form

$$q=q'E_1-q'R_1I_c \qquad (154)$$

where

$$q'=\left\|\frac{R_b}{R_1}\frac{R_L+R_f}{R_f}+\frac{R_bR_1}{R_L(R_1+R_b)}\right\|\frac{2}{\pi^2E_s} \qquad (155)$$

A relation between E_1 and E_2 can now be obtained by substituting equation 154 in equation 153 and integrating the resulting equation.

$$E_2=-K\|(1-2q'R_1I_c)E_1+q'E_1^2\|+\text{constant} \qquad (156)$$

where the constant K is the steady-state gain of the amplifier tor the linear case and is given by the expression

$$K=\frac{R_L(R_b+R_f)}{R_f(R_m+R_L)+R_b(R_f+R_L)}\cdot\frac{R_m}{R_1} \qquad (157)$$

The constant of integration may be evaluated in the following manner. When the input signal is equal to R_1I_c, the voltage waveforms are ideal. Consequently, the linear and nonlinear steady-state transfer characteristics should intersect when $E_1=R_1I_c$, provided no bias is used in either case. For the linear case and the chosen parameter values, the output voltage with no bias is given by the dashed line in Fig. 21. As seen from this figure, the output voltage is equal to 0.33 E_s when the input voltage is equal to R_1I_c. For the same parameter values the steady-state transfer characteristic for the nonlinear case becomes

$$E_2=-3.33\left\|0.577E_1+4.235\frac{1}{E_s}E_1^2\right\|+\text{constant}$$

$$=-1.92E_1-14.1\frac{1}{E_s}E_1^2+\text{constant} \qquad (158)$$

Substituting $E_1=R_1I_c=0.05\ E_s$ in equations 158 and equating the result to 0.33 E_s yields

$$\text{constant}=0.333E_s+1.92\times0.05E_s+14.1\frac{1}{E_s}(0.05E_s)^2 \qquad (159)$$

$$=0.464E_s$$

Finally, substitution of equation 159 in equation 158 gives

$$E_2=-1.92E_1-14.1\frac{1}{E_s}E_1^2+0.464E_s \qquad (160)$$

To compare the linear and nonlinear transfer characteristics, equation 160 is plotted in Fig. 21. Only a portion of the steady-state transfer characteristic can be predicted by equation 160, because it is valid only for sequence of transitions c. Sequence of transitions c occurs for input signals less than R_1I_c, and sequence b occurs for input signals greater than R_1I_c. Thus, R_1I_c is the upper limit of the input signal for which equation 160 holds. The waveform approximations are used to calculate the average inductor voltage during the intervals 0 to t_1 and t_2 to $T/2$. These time intervals, therefore, must be small compared to T. When the input voltage is equal to zero, E_1 is approximately $0.05T$ and t_2 is approximately $T/2-0.1T$. Thus, for input signals less than zero, the validity of equation 160 is questionable.

The method of determining the steady-state transfer characteristic demonstrated in the foregoing is not the only one available. For example, the equations describing the steady-state operation of the two basic amplifiers, together with the constraint equations resulting from the interconnection, may be solved directly. Since these equations are nonlinear, considerable algebraic manipulations may be involved in obtaining a solution. On the other hand, the method demonstrated not only determines the steady-state characteristic, but also the small-signal dynamic characteristic.

Summary

The analysis developed in this work is based on five characteristic properties of magnetic amplifiers:

1. Circuits are symmetrical.
2. Circuits consist of interconnections of basic elements.
3. In steady-state operation all voltages and currents are periodic and possess a common period.
4. Each inductor in an amplifier saturates only once per period.
5. For each basic element the part of the period in which the inductor is saturated is less than or equal to the part in which the inductor is unsaturated.

Properties 1 and 2 suggest an analysis in which analytic expressions for the basic elements may be combined to yield analytic expressions for the interconnected amplifier. Thus, the analysis of magnetic amplifiers may be divided into two parts: analysis of basic elements, and analysis of interconnections of basic elements. Three basic elements have been considered, as shown in Fig. 1. From an analysis point of view the first two elements are identical; they differ only in regard to the physical arrangements of components connected in series.

Properties 3, 4, and 5 allow a great simplification of the analytic expressions which determine the steady-state behavior of the basic elements. The derivation of the analytic expressions describing the basic magnetic-amplifier element of reference 1 are, in particular, greatly simplified because the circuit contains only one nonlinear element.

Because the operational cycle of magnetic amplifiers is periodic, a period of operation may be defined. For reasons of analytical simplicity, the period of operation is defined as the time interval between two successive instants in time at which the inductor becomes unsaturated. This period of operation is then divided into two equal parts: the control period and the gating period. Because the output voltage waveform is unrelated to the input voltage waveform, instantaneous values of voltage and current are almost meaningless; and half-period average voltages and currents are chosen as the circuit variables. This adoption of average-quantity variables, along with the defined period of operation, automatically introduces the concept of control- and gating-period average voltages and currents. A control-period average quantity is the average value of the quantity during the control periods; thus, it is a train of pulses where each pulse occurs during a control period and whose magnitude represents the average value that exists during the same period. Similarly, the gating-period average quantities are trains of pulses defined in a like manner for the gating periods. The sum of a control and the corresponding gating priod average voltage or current is thus equal to the actual half-period average voltage or current. The half period average voltages and currents are thus split into components represented by two pulse trains, these pulse trains being displaced from each other in time by $T/2$ sec. This expansion of a signal into a number of pulse trains may be extended by dividing the period of operation into n subintervals, the average values of the current or voltage during the subintervals being the variable quantities. Because the n subintervals repeat periodically with period T, these variable quantities are in the form of n pulse trains, the r^{th} pulse train being displaced in time by T/n sec. from the $(r+1)^{th}$. These n components are orthogonal because each component occupies its own time interval within the period of operation. Friedland employs the same type of expansion in his analysis of periodically time-varying systems, and calls these components "skip-sampled components."[5*]

During the control periods the inductor is unsaturated and its magnetizing impedance can be approximated by a linear resistance if the high permeability, square-loop-type core materials are used. For amplifiers without diodes this approximation is exceedingly good; for amplifiers with diodes the constant d-c loop width must be taken into account. However, if the voltage waveforms satisfy certain conditions, a linear resistance may be used to represent the magnetizing impedance; and, in addition, the diode may be represented as an element which is nonconducting during the control periods and conducting during the gating periods. Thus, during the control periods the basic elements are linear and resistive, and linear relations between control-period average quantities may be written. During the gating periods all components of which the basic elements are composed are linear except for the saturable inductor. Because the operation is periodic the average value of the inductor voltage over a complete period must be zero so that the relation

$$E_R^c+E_R^g=0$$

can be used to eliminate the term E_R^g from the amplifier equations. Thus, the inductor characteristics during the gating periods are immaterial as long as the amplifier possesses properties 3, 4, and 5. The resulting equations are linear relations among control and gating period average voltages and currents at the ports. From these equations, which are based on steady-state properties, the steady-state behavior of magnetic amplifiers can be obtained.

The basic element equations, when recognized as difference equations, can be used to describe the dynamic behavior of the basic elements. The manipulations that are necessary on these equations in order to determine the dynamic behavior are not as simple as for the steady-state case. If the difference equations are transformed through Laplace methods, then all manipulations are reduced to simple algebraic operations, thus simplifying the dynamic analysis. Because the difference equations describing the dynamic properties were derived from steady-state properties, these equations, in general, hold only for small changes in port voltages and currents. However, if certain waveform restrictions are satisfied, these small-change restrictions need not be adhered to; andt he transformed difference equations may be used to characterize the behavior of a magnetic amplifier for large as well as small variations in the port quantities.

To determine the analytic expressions for magnetic amplifiers resulting from interconnections of basic elements, the matrix method of determining the composite behavior, as described by Guillemin for ordinary 2-port networks, may be used.[3] This method is ideally suited for magnetic-amplifier analysis because the input and output ports of basic elements usually are isolated by transformer action. Thus, no circulating current will result from the interconnections of basic elements; this is the validity condition for the matrix method of determining the composite behavior of ordinary linear networks. For magnetic amplifiers resulting from interconnections of basic elements, an additional condition must be satisfied in order to apply the matrix method of determining the composite behavior. The control and gating periods of the individual elements must have the same position in time, or must occur so that the control period of one element corresponds in time to the gating period of the other. The symmetry property of voltage waveforms in magnetic amplifiers usually insures that this condition is satisfied. The extension of the analysis to the polyphase case clearly places in evidence the usefulness of the skip-sampled component expansion, together with the matrix method of determining the composite behavior.

For magnetic amplifiers with diodes the condition that the diodes, or diode, conduct during the gating periods and block during the control periods is not always satisfied. By approximating the voltage waveforms within the regions where this condition is violated, a set of nonlinear relations among the half-period average voltages and currents of the ports can be derived. From these nonlinear relations a set of linear differential equations can be obtained relating differential changes in the average port voltages and currents around a predetermined operating point. Since these differential equations are linear, the matrix method of determining the composite behavior is valid. The resulting differential equations may then be integrated to yield the steady-state characteristics. The small-signal dynamic characteristics are given by the differential equations. This method holds only if the regions in which the voltage-waveform approximations made are small compared to the period of operation.

Appendix I. Circuit Equations for Sequence of Transitions C

In this appendix the basic magnetic-amplifier circuit equations for sequence of transitions c are derived. The objectives

---

[*] The author had already developed the method of analysis presented in this work using the skip-sampled components as variable quantities when he became aware of Friedland's work on periodically time-varying systems.

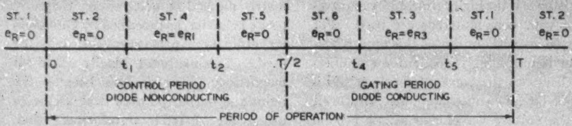

Fig. 22. Sequence of transitions c

of this derivation are twofold: to demonstrate a method by which the equations determining the steady-state or quiescent operating conditions can be obtained, and to determine the voltage waveform restrictions that make these equations linear. Even though this analysis is limited to sequence of transitions c, the method used is equally valid for any one of the other sequences of transitions; sequence of transitions c being chosen because it applies to the doubler circuit of Fig. 19.

For sequence of transitions c, see Fig. 22. Because the diode is nonconducting during the control periods and conducting during the gating periods, equations 44 through 48 are valid. The average inductor voltage during the control period, then, is the only remaining unknown; it is calculated as follows:

$$\begin{aligned}E_R^c&=\frac{2}{T}\int_0^{T/2} e_R dt\\&=\frac{2}{T}\int_0^{T/2}\|(e_1-R_1I_c)+d(e_s+e_2)\|dt-\\&\quad\frac{2}{T}\int_0^{t_1} c\|(e_1-R_1I_c)+d(e_s+e_2)\|dt-\\&\quad\frac{2}{T}\int_{t_2}^{T/2} c\|(e_1-R_1I_c)+d(e_s+e_2)\|dt\end{aligned}\tag{161}$$

where t_1 and t_2 are given by equations 26 and 34, respectively. Substitution of the waveform approximations for e_1, e_s, and e_2 in equation 161 and performing the integration yields

$$\begin{aligned}E_R^c&=c(E_1^c-R_1I_c)+d(E_s^c+E_2^c)+\\&\quad\frac{c}{T\left(\frac{R_1}{R_b}\frac{E_s}{T_s}+\frac{E_1}{T_1}\right)}(E_1'-R_1I_c)^2+\\&\quad\frac{c}{T\left\|\frac{R_1}{R_b}\left(\frac{E_s}{T_s}-\frac{E_2}{T_2}\right)+\frac{E_1}{T_1'}\right\|}\\&\qquad(E_1''-R_1I_c)^2\end{aligned}\tag{162}$$

Equation 162 shows that the half-period average inductor voltage during the control period is a nonlinear function of the slope of the output voltage (E_2/T_2) and the slopes of the input voltage (E_1/T_1 and E_1/T_1') near the zero crossings of the e_1 wave, and of the magnitude of the input voltage at times 0 and $T/2$ (E_1' and E_1'').

The equations for the basic magnetic amplifier are linear if the sum of the last two terms in equation 162 is a constant. For practical amplifiers there are only two cases of interest for which the amplifier equations are linear. These cases are:

$$E_1'=E_1''=R_1I_c \tag{163}$$

$$\left.\begin{aligned}&E_1'=\text{constant}\\&E_1''=\text{constant}\\&\frac{E_1}{T_1}=\text{constant}\\&\frac{E_1}{T_1'}=\text{constant}\\&\frac{E_2}{T_2}=\text{constant}\end{aligned}\right\}\tag{164}$$

If a d-c bias voltage is connected in series with port 1, then equation 163 becomes

$$E_1'=E_1''=R_1I_c-E_b \tag{165}$$

For $E_b=R_1I_c$ (termed ideal bias) the right-hand side of equation 165 is equal to zero. Thus, if the input voltage is zero when the supply voltage is zero and ideal bias is used, then the amplifier equations for sequence of transition c are linear. This result can be generalized for all sequences of transitions. Substitution of equation 163 in equations 20, 26, 28, 34, 35, and 36 yields

$$t_0'=t_1=t_1'=0 \tag{166}$$

$$t_2=t_2'=t_3'=T/2 \tag{167}$$

Thus, the four possible sequences of transitions in Fig. 9 reduce to the following sequence

1–4–6–3–1

The linearity condition of equation 163, therefore, applies for all four sequences of transitions.

The linearization conditions of equation 164 state that both the amplitude and the slope of the input voltage at the zero crossings of the supply voltage wave and the slope of the output voltage wave are constant or independent of the half-period average values of the input and output voltages. The output voltage waveform of resistively loaded magnetic amplifiers invariably possesses these properties. Thus, if the input voltage is obtained from another magnetic amplifier, the linearization conditions of equation 164 are usually satisfied.

Similar results may be obtained by considering any one of the other sequences of transitions. For these sequences a slight complication arises since the diode is both conducting and nonconducting during the control and gating periods. Thus, equations 45 and 47 are not valid. This difficulty can be overcome, for example, by writing equation 45 as follows:

$$E_s^c+E_2^c=R_f(I_2^c)'+R_b(I_2^c)''+E_R^c \tag{168}$$

where $(I_2^c)'$ is the half-period average current at port 2 which flows during the part of the control period in which the diode is conducting, and $(I_2^c)''$ is the half-period average current at port 2 which flows during the part of the control period in which the diode is nonconducting. The total half-period average current at port 2 is

$$I_2^c=(I_2^c)'+(I_2^c)'' \tag{169}$$

Solving equation 169 for $(I_2^c)''$ and substituting the result in equation 168 yields

$$E_s^c+E_2^c=(R_f-R_b)(I_2^c)'+R_bI_2^c+E_R^c \tag{170}$$

Because diode unblocking occurs in the intervals for which the voltage-waveform approximations are valid, the current $(I_2^c)'$ can be expressed in terms of the voltage-waveform approximations. The resulting nonlinear terms can then be combined with the nonlinear terms appearing in the expression for E_R^c.

In steady-state or quiescent operation the port voltages are periodic and of the same period as the supply voltage; equation 162 is thus valid for all periods of operation. From equations 44 through 48 and equation 162 the steady-state or quiescent relations among port voltages and currents can be derived.

If equation 163 is satisfied for all periods of operation, the following operating conditions are met:

1. The operation of the amplifier is periodic and of the same period as the supply voltage.
2. The diode is nonconducting during the control periods and conducting during the gating periods.
3. The inductor voltage is positive during the control periods.
4. The input voltage satisfies the relation

$e_1=R_1I_c$, for $t=T/2$

If these operating conditions are satisfied, then the operation of the amplifier can be described by a set of linear equations among half-period average voltages and currents.

Appendix II. Doubler Circuit

The doubler circuit of Fig. 19 is constructed of basic amplifiers *I* and *II*. In this appendix the sequences of transitions for these basic amplifiers are determined. The conditions chosen are: input of doubler is a direct voltage, supply is a sinusoidal voltage, and a resistive load. The voltage waveform approximations that can be made for sequence of transitions c are then determined, and in the end a discussion of the circuit behavior in the limiting case when $R_m\rightarrow\infty$ is given.

The state of the basic amplifier depends upon the supply and port voltages. Because the doubler circuit is constructed by connecting two basic amplifiers in series-parallel, the input port voltage of basic amplifier *I* is the sum of the direct input voltage to the doubler circuit and the voltage that exists across the control winding of basic amplifier *II*; the output port voltage of each basic amplifier, however, is the same as the output voltage of the doubler circuit.

The currents that flow in the doubler cir-

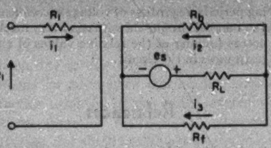

Fig. 23. Equivalent circuit at time zero

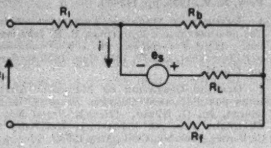

Fig. 24. Approximate equivalent circuit in interval 0 to t_1

cuit, when the supply voltage is zero, are caused by the input voltage only. If the input voltage magnitude is less than R_1I_c, the inductor voltages are zero. A small increase or decrease in the supply voltage, therefore, causes one diode to conduct and the other to block. Thus, the states of the diodes depend entirely upon the supply voltage. A further increase or decrease in the supply voltage causes currents of sufficient magnitude to overcome the loop-width current I_c to flow through the inductors. A voltage now appears across each inductor, driving one towards and the other away from saturation. The events just described correspond to sequence of transitions c. By a similar argument, it can be shown that sequence of transitions b occurs if the input voltage is greater than R_1I_c.

The voltage-waveform approximations for sequence of transitions c will now be determined. The intervals of interest are from time zero to t_1, and from t_2 to $T/2$. An equivalent circuit at time 0+ is shown in Fig. 23. Because R_b is large compared to R_L and R_f, the three loop currents are given by the following equations.

$$i_1=\frac{e_1}{R_1} \tag{171}$$

$$i_2=\frac{e_s}{R_b} \tag{172}$$

$$i_3=\frac{e_s}{R_L+R_f} \tag{173}$$

At time t_1 the net current in inductor I is equal to I_c. The equivalent circuit of Fig. 23, however, is valid only if

$$i_3-i_1<i_1+i_2<I_c \tag{174}$$

Because R_L and R_f are small compared to the other resistances in the circuit, the current i_3-i_1 builds up rapidly and, if $i_1=I_c$, will reach the magnitude I_c at time

$$t_x=\frac{2I_c(R_L+R_L)}{\pi^2E_s}T \tag{175}$$

The time given by equation 175 is the maximum time it takes the current i_3-i_1 to reach I_c. For most practical amplifiers $I_c(R_L+R_f)<0.01\ E_s$ so that

$$t_x<0.002T \tag{176}$$

The time interval from zero to t_x, therefore, is negligible. The time t_1, then, can be determined from the equivalent circuit shown in Fig. 24. The current i can be expressed as follows

$$i=\frac{R_1+R_b}{(R_1+R_f+R_L)R_b}e_s+\frac{1}{R_1+R_L+R_f}e_1 \tag{177}$$

Substituting $e_s=(\pi^2/T)E_st_1$, $e_1=E_1$, and $i=I_c$ in equation 177 and solving for the time t_1 yields

$$t_1=\frac{T}{\pi^2E_s}\frac{R_b}{R_1+R_b}\times \left\|(R_1+R_f+R_L)I_c-\frac{1}{R_1}E_1\right\| \tag{178}$$

If R_1 is of the same order of magnitude as R_f and R_L, the time t_1 is small and may be neglected. Thus, only when R_1 is large compared to R_f and R_L is the time interval from 0 to t_1 of importance; and the approximation that R_1 is large compared to R_f and R_L can be made. Equations 177 and 178 can then be rewritten as follows:

$$i=\frac{1}{R_b}e_s+\frac{1}{R_1}(e_s+e_1) \tag{179}$$

$$t_1=\frac{T}{\pi^2E_s}\frac{R_b}{R_1+R_b}(R_1I_c-E_1) \tag{180}$$

From equations 179 and 180 the voltage-waveform approximations for the time interval from 0 to t_1 become:

$$\frac{E_s}{T_s}=\frac{\pi^2}{T}E_s \tag{181}$$

$$\frac{E_1}{T_1}=\frac{\pi^2}{T}E_s \tag{182}$$

$$E_1'=E_1 \tag{183}$$

An equivalent circuit for the time interval from t_2 to $T/2$ is shown in Fig. 25(A). The waveform approximations then become:

$$\frac{E_s}{T_s}=\frac{\pi^2}{T}E_s \tag{184}$$

$$\frac{E_s}{T_s}=\frac{R_L}{R_L+R_f}\frac{\pi^2}{T}E_s \tag{185}$$

$$\frac{E_1}{T_1'}=0 \tag{186}$$

$$E_1''=E_1 \tag{187}$$

These waveform approximations can be used to determine the average inductor voltage during the control period.

An interesting case arises when R_m is large compared to the other resistances in the circuit. In the analysis that follows ideal waveforms and zero loop width are assumed. These assumptions normally imply that the diodes are nonconducting and conducting respectively during the control and gating periods of their associated inductors. The half-period average input voltage for minimum and maximum output voltage can then be obtained as follows.

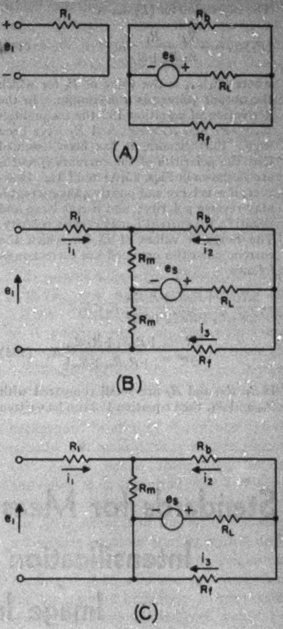

Fig. 25. Equivalent circuit

A—In interval t_2 to T/2
B—When the inductors are unsaturated
C—When one inductor is saturated

Minimum output voltage occurs when neither of the two inductors saturate. This condition is insured if

$$E_{RI}=-E_{RII} \tag{188}$$

The average value of the input voltage for which equation 188 is satisfied can readily be obtained from the equivalent circuit of Fig. 25(B) and is

$$(E_1)_{\min}=\frac{R_1(R_b-R_f)}{(R_f+R_b)(2R_L+R_m+R_b)-R_b(R_b-R_f)}E_s \tag{189}$$

where $(E_1)_{\min}$ is the value of E_1 for which the output voltage is a minimum. Making use of the inequality $R_b>>R_f$ in equation 189 yields

$$(E_1)_{\min}\cong\frac{R_1}{2R_L+R_m}E_s \tag{190}$$

The average value of e_1 for which maximum output voltage is obtained can be determined from the equivalent circuit of Fig. 25(C) and the equation

$$E_{RI}=E_{RII}=0 \tag{191}$$

The expression for $(E_1)_{max}$ is

$$(E_1)_{max} = -\frac{R_f}{R_b}\frac{R_1}{R_L+R_f}E_s \qquad (192)$$

where $(E_1)_{max}$ is the value of E_1 for which the output voltage is a maximum. In the derivation of equation 192 the inequalities $R_m >> R_L$ and $R_f >> R_L$ and R_f have been used. Furthermore, it has been assumed that the polarities of the currents i_2 and i_3 are as shown in Figs. 25(A) and (B). However, if e_1 is large and positive, the current i_2 may reverse polarity; and if e_1 is large and negative, the current i_3 may reverse polarity. The range of values of E_1 for which the current polarities assumed are correct is as follows

$$-\frac{2R_bR_m+R_bR_1+R_1R_m}{2R_LR_m+R_bR_m+R_m^2}E_s < E_1 < \frac{2R_fR_m+R_bR_1+R_LR_m}{2R_LR_m+R_fR_m+R_m^2}E_s \qquad (193)$$

If R_1, R_L, and R_f are small compared with R_m and R_b, then equation 193 can be written

$$-\frac{2R_b}{R_b+R_m}E_s < E_1 < \left\| \frac{2R_f+R_1}{R_m} + \frac{R_bR_1}{R_m^2} \right\| E_s \qquad (194)$$

The useful range of E_1 (range for which the output can be controlled by the input) is obtained from equations 190 and 192, and is

$$-\frac{R_f}{R_b}\frac{R_1}{R_L+R_f}E_s < E_1 < \frac{R_1}{2R_L+R_m}E_s \qquad (195)$$

Because $R_L << R_m$, the right-hand side of equation 194 is always greater than the right-hand side of equation 195. Thus, i_3 is always positive within the useful range of e_1. The left-hand side of equation 193, however, may, if R_m is sufficiently large, be greater than the left-hand side of equation 195. Thus, i_1 may be negative. In the limit when $R_m \to \infty$ both sides of equation 193 are zero, while only the right-hand side of equation 195 is zero. Consequently, if the saturable inductor is ideal, the diodes conduct during the control periods and block during the gating periods, regardless of voltage waveforms. In practical circuits this situation very rarely occurs because of the relative values of the resistances in the circuit.

Standards for Measurement of Brightness Intensification in Fluoroscopic Image Intensifiers

WALTER S. LUSBY
ASSOCIATE MEMBER AIEE

IT IS convenient to characterize devices for production of intensified X-ray fluoroscopic images in terms of their brightness as compared with conventional fluoroscopic screens. Thus, an X-ray image intensifier is described having an intensification factor of 200 or 500 or 1,000 meaning that the image presented to the viewer is 200 or 500 or 1,000 times brighter than the image would be if he used a conventional X-ray screen. These figures, although widely used today, are meaningless unless all variables are defined and standardized in their measurement. Furthermore, the same term has been used to express the brightness relationship between a light image from a phosphor at the input end of an image device and the light image output. In the case of a fluorescent screen contiguous to a photoelectric surface in a vacuum, the input light image used as the base point can be quite different from, and is usually less bright than, the conventional fluoroscopic screen image under equal stimulus. However, to the best of the author's knowledge, no previous attempt has been made to propose a set of standard conditions on which to base a figure of merit for X-ray image intensifiers.

There are many factors which can lead to variations in the figure of merit for image intensification. First, based on a comparison with a conventional screen, there is the question of how bright the conventional X-ray screen is. The early literature on medical X-ray intensiffers refers to the intensification factor required for success. Obviously the comparison was with a much less bright screen than the conventional screen of today. The industry has progressed from what has been posthumously named the Patterson *A* fluoroscopic screen to the *B*, the *B2*, and the *CB2*, as well as to the screens of other manufacturers, and a steady increase in the brightness of conventional fluoroscopic screens has been witnessed. For example, since the introduction of the Patterson *B* screen in 1934 the average brightness of Patterson fluoroscopic screens has increased by approximately 300%.

Second, the effective wavelength or hardness of the X-ray beam affects the comparisons. Some types of image intensifiers employ a construction such as a heavy glass window in the X-ray beam which acts as a substantial filter. It follows that a comparison of speed of the conventional and the new devices can easily vary by a factor of 2 depending upon the kilovoltage at which the measurements are made.

Third, one can compare brightness by using an open X-ray beam or by using a simulated or actual patient or industrial object. Again a substantial variation in results is obtained.

The need for standards for intensification factors rests not only on technical grounds of scientific correctness, but also on practical grounds. For example, one may attempt to extrapolate cinefluorographic techniques from one type of image intensifier to another using the intensification factors published by the manufacturers and compensating for all other variables. The predicted exposure factors may appear to disagree by more than 2 to 1. In the opinion of the author, this is a direct result of the lack of an accepted common standard and thus there should be unaminous agreement that some form of standard is necessary.

Paper 57-316, recommended by the AIEE Electrical Techniques in Medicine and Biology Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted April 26, 1957; made available for printing December 30, 1958.

Walter S. Lusby is with the Westinghouse Electric Corporation, Baltimore, Md.

Another question to be considered is what standard to use. It is not practical to propose a standard which would vary from day to day depending on improvements in phosphors and screen manufacture achieved by the manufacturers of conventional fluoroscopic screens. Rather, one should establish a permanent base line and refer both intensified fluoroscopic images and images from improved conventional screens to this same base line.

For the medical field, the conditions under which the comparisons are made should be simulated clinical conditions. There is considerable latitude for arbitrary choice. The author would like to propose that an X-ray tube voltage of approximately 80 pkv (peak kilovolts) be used for the purpose of the standard. Although techniques tend to shift up or down in kilovoltage over a period of years, 80 pkv appears to be a comfortable midpoint in the range of typical fluoroscopic techniques. For reasons of repeatability of test results a fairly homogeneous X-ray beam is desirable. We use and recommend a 2-cm (centimeters) aluminum filter at the X-ray tube for this purpose. To be more specific and to rule out variations due to generator waveform, length of shockproof cables, etc., it is proposed that this be specified as an X-ray beam with half-value layer of 6.5 millimeters of aluminum obtained with an X-ray tube voltage of 80 pkv±4 pkv.

Another condition to be specified is whether or not a patient is in the beam during measurement, and if so, the patient's thickness. It is proposed that a patient-equivalent phantom be used as close as practical to the image intensifier device, in addition to the filter used at the tube to obtain a homogeneous beam. It is further proposed that the comparisons for the pupose of determining intensification factor be made in three parts representing patient thicknesses near the extremes and center of the absorptions provided by clinical work, and that filters of 2, 4, and 6 cm of 99% pure aluminum be used. These correspond approximately to 10, 20, and 30 cm of boneless solid body tissue.

The author has worked with prestwood phantoms and certainly finds them useful as patient-equivalent filters. Prestwood does vary in density, however, over a fairly substantial range. In addition, the fact that aluminum is less bulky is an advantage.

The X-ray beam should be limited by coning and other precautions should be taken to minimize the effects of scattered radiation. Obviously, the filters which are used as absorbers should extend well beyond the actual cross section of the X-ray beam.

A standard or reference distance from the X-ray source to the fluoroscopic device must be selected. If about 20 cm are allowed between the table top and the screen and the typical 18-inch target-to-table top distance is used, then a target-to-screen distance of 66 cm is selected. It is proposed that this 66 cm be taken as the distance to the outer projection of the device being measured. In other words, assume that a conventional fluoroscopic screen is used with a holder of negligible thickness in contact with the patient at 66 cm from the X-ray tube target. Assume that the device being measured is brought up to this imaginary patient. In some instances, such as in the Westinghouse Fluorex image intensifier, the active input screen will be located more than 66 cm from the X-ray source.

It is proposed that 2 milliamperes of X-ray tube current be accepted as a good practical basis for establishing standard brightness values, and that this be further corrected, if necessary, to provide 94 milliroentgens per minute at 66 cm, measured without backscatter. It is also proposed that the measurements be made at 20 degrees centigrade ±5 degrees and corrected to 20 degrees centigrade.

Because of the extremely low levels of birghtness involved, brightness measurements are difficult, and because the visual mechanism is dual in nature there is an additional problem of color response. At one end of the range of brightness in which we are interested cone vision predominates and color can be seen. At the other end of the range of brightness of interest, rod vision predominates and the eye perceives no color. The use of standard light-measuring instruments such as the Macbeth illuminometer are tedious and are subject to some inaccuracies. It is obvious that in any routine testing one must get away from these basic instruments and provide an instrument which presents a result such as, for example, an electric instrument reading. Still, at one stage of calibration one must rely on light comparisons made by the eye. As a result of many thousands of readings it is proposed that the brightness of conventional fluoroscopy under the proposed conditions be defined at the three specified thicknesses as 8.5, 1.3, and 0.20 microlamberts at 2, 4, and 6 cm of aluminum, respectively.

It is not to be inferred that these numbers, and only these numbers, are satisfactory. A standard would be welcome which uses these or any other logical numbers. Actually, these data represent typical or average screens at the time the data were established several years ago.

With regard to industrial fluoroscopy although its range is somewhat broader than the medical range, the standard as proposed for determining the intensification factor is quite appropriate also for the industrial field.

It is proposed that the same standards be used for all fluoroscopic intensifiers.

To establish the intensification factor of a device one would then proceed as follows. Measure the brightness out-put of the device with the 2-cm aluminum phantom and the standard 80-kv beam at 2 milliamperes and 66-cm target device distance. Turn off the X-ray source and immediately measure the residue or background brightness, if any, and determine by subtraction the brightness due to the X-ray image alone. To avoid ambiguity it is suggested that a residue reading be defined as the value at 1 second after removal of the beam following a 1-minute exposure starting with a dark device. Assume that the brightness reading is 4.25 millilamberts and that the background brightness is zero; then divide the 4.25-millilambert value by 0.0085 and arrive at the intensification factor of 500. The same process is repeated for the 4-cm and 6-cm aluminum phantoms. The three figures are averaged to obtain the standard intensification factor.

One result of adopting this proposed standard would be that all measurements could be made at levels corresponding to the photopic eye and so the photometer used should be designed to have a frequency response corresponding to the response of the photopic eye. The difficulty of measurement of light values in a range near 1 millilambert is significantly less than the difficulty of measurements at the normal fluoroscopic brightnesses. Therefore, the agreement on a standard such as proposed here would provide not only real significance to statements of intensification factor, but also would provide greater accuracy.

Discussion

J. E. Jacobs (General Electric Company, Milwaukee, Wis.): Mr. Lusby is to be commended for recognizing the situation that exists today regarding the relative intensification factors of commercially available X-ray image intensifiers. While his proposal is a thorough and comprehensive one relating to the image-converter-type amplifier, it does not in my opinion have the basic criterion of a standard, i.e., a measurement related to the fundamental processes involved.

To correct this we propose that the standard, when adopted, relate the image obtainable of a given system under a standard set of conditions to that obtainable under the same conditions by a theoretically perfect amplifier, i.e., one whose image quality is limited only by the statistics of the X-ray image process itself. Computations and studies along these lines are well known and documented.[1-3]

Using this concept of the "ideal amplifier" as the basis for excellence of a particular system, all forms of X-ray image reproduction may be readily compared. This approach has the added advantage of being adaptable to new systems as they are devised.

Unless such a method of standardization is adopted we will be faced with the necessity of devising new standards each time a new system becomes available.

The Use of Iterated Laplace Transformations in the Solution of Combined Circuit-Field Problems

J. H. MULLIGAN, JR.
MEMBER AIEE

Synopsis: By consideration of a detailed example, the use of iterated Laplace transformations is shown to be an important technique for the solution of combined circuit-field problems, i.e., problems in which the simultaneous solution of ordinary and partial differential equations is necessary. One- and 2-mesh circuits in which eddy currents in a rectangular magnetic core play a significant role are analyzed utilizing the iterated transformations; equivalent circuits characterizing the effect of the eddy currents are also presented.

PROBLEMS sometimes arise in electric circuit theory where both ordinary and partial differential equations must be solved simultaneously in order to provide a rigorous solution to the complete physical problem. In general, the boundary conditions for the partial differential equations will contain unknown quantities which are variables with respect to time in one or more ordinary differential equations associated with the physical system involved. Problems of this kind will be identified as combined circuit-field problems.

A technique that seems particularly suitable for solving problems of the combined circuit-field variety is one using iterated Laplace transformations.[1] By this method, the solution to the partial differential equation(s) may be expressed in terms of the transforms with respect to time of the variables in the ordinary differential equations. This process leads in turn to straightforward simultaneous solution of the (transformed) ordinary differential equations and subsequent direct determination of the desired functions of time.

This paper illustrates the use of the iterated transform technique in the consideration of an example containing 1- and 2-mesh electric circuits which interact with a magnetic core. In addition to the normal circuit equations, the problem requires the solution of a partial differential equation in two space dimensions for a complete description of the electric and magnetic effects involved.

A typical example which involves both field and circuit equations is the eddy current problem which may be formulated with the aid of Fig. 1. (It is of interest to note that although the eddy current problem or one closely related has been treated in detail previously by several investigators, no reference has been found by the writer which treats the problem for a rectangular lamination without the a priori assumption that the problem is one-dimensional rather than the 2-dimensional one which is considered here; see, for example, references 2–9.) A coil of N turns is wound on a re-entrant core of rectangular cross section (area of magnetic material $=A$ square meters) formed from M laminations of width w (meters) and height d (meters). The core, which is of length r (meters), is assumed to be wound uniformly with the N turns. In the range of circuit current values encountered, the magnetic material is assumed to have a constant permeability of μ henrys per meter and a conductivity of σ mhos per meter.

The switch S, which is assumed to have been closed for a sufficient period of time for the current in the coil to have come to equilibrium, is opened at time $t=0$. The current in the coil experiences no discontinuity when the switch is opened; its initial value, assumed known, is designated $i(0^+)$ as indicated in the figure.

Associated with the current in the coil is the storage of energy in the magnetic field produced by the current. When switch S is opened, the stored magnetic energy cannot be dissipated instantly in the absence of a sink capable of absorbing energy at an infinite rate. Consequently, an attempt to change the current in the coil and thus the flux in the magnetic core from their values just prior to opening the

Paper 59-227, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted November 3, 1958; made available for printing December 3, 1958.

J. H. MULLIGAN, JR., is with New York University, New York, N. Y.

A portion of the work reported herein was done by the author as a consultant to the Bell Telephone Laboratories, Inc., New York, N. Y.

switch results in the production of induced electromotive forces. The latter cause the well-known eddy currents in the magnetic material comprising the core. The decay of current $i(t)$ is thus dependent not only on the nature of the external circuit, in this case composed of the resistor R, but also on the properties of the coil and the core on which it is wound. The potential across the coil can be combined with that across R to obtain a Kirchhoff voltage law equation involving $i(t)$. On the other hand, this potential is a function of the magnetic flux density in the core, a quantity which is related to the current in the coil through a partial differential equation.

Subject to the assumption that conditions in the re-entrant core are well approximated by those in a 2-dimensional model, the flux in the core Φ, the current $i(t)$, and the magnetic field intensity $H(x,y,t)$ are related as follows: (This analysis does not take into account the effects of spin relaxation damping on the decay of flux in the magnetic material. Indications are that whereas this effect is important at lamination thicknesses of 1/4 and 1/8 mil in *4-79* Molybdenum-Permalloy, the classical eddy currents provide the predominant effect in samples of material of approximately 1 mil and greater thickness; see, for example, references 10–11.

$$Ri(t)+N\frac{d\Phi}{dt}=0 \tag{1}$$

where

$$\frac{d\Phi}{dt}=M\frac{d}{dt}\int_0^w\int_0^d B(x,y,t)dydx$$
$$=M\int_0^w\int_0^d \frac{\mu\partial H(x,y,t)}{\partial t}dydx \tag{2}$$

and $H(x,y,t)$ satisfies

$$\frac{\partial^2 H(x,y,t)}{\partial x^2}+\frac{\partial^2 H(x,y,t)}{\partial y^2}=\mu\sigma\frac{\partial H(x,y,t)}{\partial t} \tag{3}$$

plus the initial and boundary conditions

$$H(x,y,0)=\frac{Ni(0^+)}{r} \tag{4}$$

$$H(x,y,t)=\frac{Ni(t)}{r} \tag{5}$$

at $x=0$, w and $y=0$, d.

The quantities M, w, and d are the number, width, and height of the laminations; the co-ordinate system assumed for representation of the laminations is shown in Fig. 2. Conditions 4 and 5 result by considering the line integral of $H(x,y,t)$ around a path enclosing one lamination which, by successive expansion of path, may be shown to be equal to the line integral of $H(x,y,t)$ around the stack of M laminations.

It is convenient to introduce the space average of $H(x,y,t)$ over the cross section of a single lamination. Denoting this quantity by $H_{avg}(t)$, then by definition,

$$wdH_{avg}(t)=\int_0^w\int_0^d H(x,y,t)dydx \tag{6}$$

and equation 1 can now be written

$$Ri(t)+\mu AN\frac{dH_{avg}(t)}{dt}=0 \tag{7}$$

where

A = total cross-sectional area of magnetic material in the core

To determine $i(t)$, equations 3 and 7 must be solved simultaneously subject to conditions 4 and 5. To effect the solution, it is convenient to utilize iterated Laplace transforms. First, the transform of the two equations with respect to time is taken which converts equation 7 to an algebraic equation and leaves equation 3 containing only derivatives with respect to x and y. Laplace transformation of the transformed equation 3 with respect to x then yields an ordinary differential equation in y. Solution of this equation and subsequent inversion of the transform equation yields a transform solution for H (with only time transformed) that may be solved simultaneously with the transform of equation 7 to find $i(t)$.

Formulation and Solution of Transform Equations

Laplace Transformation With Respect to Time

Let the Laplace transforms of $H_{avg}(t)$ and $i(t)$ be denoted as $\bar{H}_{avg}(s)$ and $I(s)$ where

$$\bar{H}_{avg}(s)=\mathfrak{L}[H_{avg}(t)]=\int_0^\infty H_{avg}(t)\epsilon^{-st}dt$$

and

$$I(s)=\mathfrak{L}[i(t)]=\int_0^\infty i(t)\epsilon^{-st}dt$$

Taking the Laplace transform of equation 7 then produces

$$RI(s)+\mu AN[s\bar{H}_{avg}(s)-H_{avg}(0^+)]=0 \tag{8}$$

Utilizing condition 4 and the defining equation for self-inductance $L=\mu N^2A/r$, equation 8 can be written in the form

$$RI(s)+\mu ANs\bar{H}_{avg}(s)=Li(0^+) \tag{9}$$

Once $\bar{H}_{avg}(s)$ can be expressed as a function of $I(s)$, equation 9 will permit solution for $I(s)$, which upon inversion, yields $i(t)$. Since $i(t)$ is involved in the boundary conditions for the partial differential equation 3, the desired expression for $\bar{H}_{avg}(s)$ can be obtained by solving that equation in transform form.

Taking the Laplace transform of equation 3 and the initial and boundary conditions 4 and 5 yields

$$\frac{\partial^2\bar{H}(x,y,s)}{\partial x^2}+\frac{\partial^2\bar{H}(x,y,s)}{\partial y^2}=\mu\sigma\bar{H}(x,y,s)-\mu\sigma\frac{Ni(0^+)}{r} \tag{10}$$

and

$$\bar{H}(x,0,s)=\bar{H}(x,d,s)=\bar{H}(0,y,s)=\bar{H}(w,y,s)=\frac{NI(s)}{r} \tag{11}$$

where

$$\bar{H}(x,y,s)=\mathfrak{L}_t[H(x,y,t)]=\int_0^\infty H(x,y,t)\epsilon^{-st}dt$$

Solution of Equation for $\bar{H}(x,y,s)$

The Laplace transform of the function $\bar{H}(x,y,s)$ with respect to the variable x is defined as

$$\mathfrak{L}_x[\bar{H}(x,y,s)]=H^*(z,y,s)=\int_0^\infty \bar{H}(x,y,s)\epsilon^{-zx}dx$$

Transforming equations 10 and 11 results in the expressions

$$\frac{d^2H^*(z,y,s)}{dy^2}+(z^2-\mu\sigma s)H^*(z,y,s)=z\frac{NI(s)}{r}-\mu\sigma\frac{Ni(0^+)}{r}+\varphi(y,s) \tag{12}$$

$$H^*(z,0,s)=H^*(z,d,s)=\frac{NI(s)}{rz} \tag{13}$$

In equation 12 the partial derivative with respect to y has been replaced by an ordinary derivative and $\varphi(y,s)$ has been used to designate the function, as yet unknown,

$$\frac{\partial\bar{H}(x,y,s)}{\partial x}$$

evaluated at $x=0$.

The solution of equation 12 subject to the boundary conditions (equation 13) is[1,12]

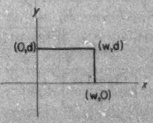

Fig. 2. Geometry of core cross section

$$H^*(z,y,s)=\frac{zNI(s)}{r(z^2-\mu\sigma s)}-\frac{\mu\sigma Ni(0^+)}{rz(z^2-\mu\sigma s)}+$$
$$\frac{1}{\sin d\sqrt{z^2-\mu\sigma s}}\left\{\left[-\frac{NI(s)z}{r(z^2-\mu\sigma s)}+\frac{\mu\sigma Ni(0^+)}{rz(z^2-\mu\sigma s)}+\frac{NI(s)}{rz}\right]\times\right.$$
$$\left.\left[\sin y\sqrt{z^2-\mu\sigma s}+\sin(d-y)\sqrt{z^2-\mu\sigma s}\right]\right\}-$$
$$\frac{1}{\sin d\sqrt{z^2-\mu\sigma s}}\left\{\frac{\sin y\sqrt{z^2-\mu\sigma s}}{\sqrt{z^2-\mu\sigma s}}\int_y^d\varphi(\eta,s)\sin(d-\eta)\sqrt{z^2-\mu\sigma s}\,d\eta+\right.$$
$$\left.\frac{\sin(d-y)\sqrt{z^2-\mu\sigma s}}{\sqrt{z^2-\mu\sigma s}}\int_0^y\varphi(\eta,s)\sin\eta\sqrt{z^2-\mu\sigma s}\,d\eta\right\}\qquad(14)$$

The function $\bar{H}(x,y,s)$ is to be determined from $H^*(z,y,s)$ by the inverse Laplace transformation, namely

$$\bar{H}(x,y,s)=\mathfrak{L}_z^{-1}[H^*(z,y,s)]$$
$$=\frac{1}{2\pi j}\int_{c-j\infty}^{c+j\infty}H^*(z,y,s)\epsilon^{zx}dz\qquad(15)$$

This integral can be evaluated utilizing contour integral techniques, but to do so, the nature and location of the singularities of the integrand must be known. Detailed examination of the terms that comprise $H^*(z,y,s)$ indicates that only simple poles are present. The pole locations and the residues of $\epsilon^{zx}H^*(z,y,s)$ in these poles will be considered on a term by term basis.

Examination of the behavior of the first, second, and third terms in the expression for $H^*(z,y,s)$ indicates that a removable singularity exists at $z=\pm\sqrt{\mu\sigma s}$. No other singularity results from the first term, although the pole at $z=0$ in the second term contributes an amount $Ni(0^+)/sr$ as the residue of $\epsilon^{zx}H^*(z,y,s)$ in this pole. The corresponding contribution of the pole at $z=0$ in the third term is

$$\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{rs}\right]\times$$
$$\left[\frac{\sinh y\sqrt{\mu\sigma s}+\sinh(d-y)\sqrt{\mu\sigma s}}{\sinh d\sqrt{\mu\sigma s}}\right]$$

The third term also has simple poles at

$$z=\pm\sqrt{\frac{(2n-1)^2\pi^2}{d^2}+\mu\sigma s}\ (n=1,2,3,\ldots)$$
$$\text{for } y\neq 0,\ y\neq d$$

which contributes the following amount to the evaluation of the integral:

$$4\frac{\mu\sigma s}{(2n-1)\pi}\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{sr}\right]\times$$
$$\frac{\sin\frac{(2n-1)\pi y}{d}\cosh x\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}}{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}$$

The fourth and fifth terms have simple poles at

$$z=\pm\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}\ (n=1,2,3,\ldots)$$
$$\text{for } y\neq 0,\ y\neq d$$

resulting in the contribution of the following term:

$$\sin\frac{n\pi y}{d}\sinh x\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}\times$$
$$\frac{2}{d}\frac{\int_0^d\varphi(\eta,s)\sin\frac{n\pi\eta}{d}d\eta}{\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}}$$

With a knowledge of the poles of $H^*(z,y,s)$ and the residues of $\epsilon^{zx}H^*(z,y,s)$ in the poles, as well as the realization that $H^*(z,y,s)$ vanishes as z becomes infinite, the theorem of residues may be applied directly to the evaluation of equation 15. Combining the residues just obtained, it is found that

$$H(x,y,s)=\frac{Ni(0^+)}{rs}+\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{rs}\right]\left[\frac{\sinh y\sqrt{\mu\sigma s}+\sinh(d-y)\sqrt{\mu\sigma s}}{\sinh d\sqrt{\mu\sigma s}}\right]+$$
$$\mu\sigma s\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{rs}\right]\frac{4}{\pi}\sum_{n=1}^{\infty}\frac{1}{2n-1}\frac{1}{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}\times$$
$$\cosh x\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}\ \sin\frac{(2n-1)\pi y}{d}+$$
$$\sum_{n=1}^{\infty}\frac{g_{n(s)}}{\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}}\sinh x\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}\ \sin\frac{n\pi y}{d}\qquad(16)$$

where

$$g_n(s)=\frac{2}{d}\int_0^d\varphi(\eta,s)\sin\frac{n\pi\eta}{d}d\eta\qquad(17)$$

and $y\neq 0$, $y\neq d$.

When $y=0$ or $y=d$, the poles from which the third and fourth terms were derived vanish, so that $\bar{H}(x,y,s)$ reduces to the one term $NI(s)/r$ as it should. The function $\varphi(\eta,s)$ may be replaced by a known quantity by the use of one of the boundary conditions 11, namely $\bar{H}(w,y,s)=NI(s)/r$. For the evaluation, the second term of equation 16 is expanded in a Fourier sine series and then with x set equal to w, expression 16 is set equal to $NI(s)/r$ in view of the boundary condition cited. This results in the following equality:

$$1=\frac{4}{\pi}\sum_{n=1}^{\infty}\frac{1}{2n-1}\times$$
$$\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s\cosh w$$
$$\frac{\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}}{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}\times$$
$$\sin\frac{(2n-1)\pi y}{d}+\frac{4}{\pi}\sum_{n=1}^{\infty}a_n$$
$$\sinh w\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}\ \sin\frac{n\pi y}{d}$$

where

$$a_n=\frac{\pi}{4}\frac{g_n(s)}{\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{rs}\right]\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}}$$

Replacing the factor unity on the left-hand side of the equation by the Fourier sine series,

$$1=\frac{4}{\pi}\sum_{n=1}^{\infty}\frac{1}{2n-1}\sin\frac{(2n-1)\pi y}{d},\ 0<y<d$$

and equating coefficients, produces the final result

$$a_n=0\ (n\text{-even})$$

$$a_n=\frac{\mu\sigma s}{n}\times$$
$$\frac{\left[1-\cosh w\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu s}\right]}{\left[\left(\frac{n\pi}{d}\right)^2+\mu\sigma s\right]\sinh w\sqrt{\left(\frac{n\pi}{d}\right)^2+\mu\sigma s}}$$
$$(n\text{-odd})$$

The substitution of the last-named result in equation 16 allows the equation for $H(x,y,s)$ to be simplified to the form

$$H(x,y,s)=\frac{Ni(0^+)}{rs}+\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{rs}\right]\frac{4}{\pi}\times$$

$$\sum_{n=1}^{\infty}\frac{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s\left[\frac{\sinh x\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}+\sinh(w-x)\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}}{\sinh w\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}}\right]}{(2n-1)\left[\frac{(2n-1)^2\pi^2}{d^2}+\mu\sigma s\right]}\times$$

$$\sin\frac{(2n-1)\pi y}{d} \qquad (18)$$

Equation 18 is of considerable interest inasmuch as it expresses the transform of $H(x,y,t)$ in terms of the known initial value of $i(t)$ and the transform of $i(t)$. If, for example, the current in the coil wound on the core is forced to have a certain known time variation, equation 18 allows the direct determination of the magnetic field as a function of time at all points in the cross section of the core. On the other hand, formulation of $H(x,y,s)$ in terms of $I(s)$ as in equation 18 permits determination of $I(s)$ as well as the magnetic field in a problem such as the one under consideration where equations must be solved simultaneously to obtain the two functions.

Before proceeding to the calculation of $\bar{H}_{avg}(s)$ and the solution for $I(s)$, it is of interest to examine the variation of $\bar{H}(x,y,s)$ in various limiting situations. At the boundaries $x=0$ and $x=w$, it is clear that the numerator cancels all but the factor n in the denominator of the second term. The series that remain sums to unity with the result that $\bar{H}$ goes to $NI(s)/r$ as it should. For $y=0$ and $y=d$, it has already been mentioned in connection with equation 16 that $\bar{H}(x,y,s)=NI(s)/r$. Finally, the behavior of $H(x,y,t)$ as t approaches zero or becomes infinite can be found from equation 18 by the limiting processes

$$H(x,y,0)=\lim_{s\to\infty}s\bar{H}(x,y,s)$$

$$H(x,y,\infty)=\lim_{s\to 0}s\bar{H}(x,y,s)$$

In connection with the first limiting process, it is seen from equation 18 that the factor containing the hyperbolic sines approaches zero ($x\neq 0\neq w$) as s becomes infinite with the result that

$$H(x,y,0)=\lim_{s\to\infty}s\bar{H}(x,y,s)=\frac{Ni(0^+)}{r}$$

Similarly, as s approaches zero, the second term in equation 18 approaches the Fourier sine series for unity with the result

$$H(x,y,\infty)=\lim_{s\to 0}s\bar{H}(x,y,s)$$

$$=\lim_{s\to 0}\left[\frac{Ni(0^+)}{r}+\frac{NsI(s)}{r}-\frac{Ni(0^+)}{r}\right]$$

$$=\frac{Ni(\infty)}{r}$$

These results are in accordance with the stated initial condition and the physical nature of the final condition for the equation.

DETERMINATION OF $I(s)$

The average value of $\bar{H}(x,y,s)$ over the cross section of the rectangular region bounded by the lines $x=0$, $x=w$ and $y=0$, $y=d$ is defined as

$$wd\bar{H}_{avg}(s)=\int_0^w\int_0^d\bar{H}(x,y,s)dydx$$

which, when applied to equation 18, yields

$$\bar{H}_{avg}(s)=\frac{Ni(0^+)}{rs}+\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{rs}\right]\frac{8}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{(2n-1)^2}\times$$

$$\frac{\frac{(2n-1)^2\pi^2}{d^2}+\mu\sigma s\frac{\tanh\frac{w}{2}\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}}{\frac{w}{2}\sqrt{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s}}}{\left[\frac{(2n-1)\pi}{d}\right]^2+\mu\sigma s} \qquad (19)$$

An examination of the second term in equation 19 reveals that the term in the expansion for each value of n is a function which has only poles on the negative real axis with zeros on that axis which separate the poles. The poles are located at

$$s=-\rho_{mn}=-\frac{\pi^2}{\mu\sigma}\left[\frac{(2n-1)^2}{d^2}+\frac{(2m-1)^2}{w^2}\right];$$

$$m,n=1,2,3,\ldots \qquad (20)$$

with residues (for the function inside the summation sign)

$$k_{mn}=\frac{8}{\mu\sigma}\left[\frac{1}{(2n-1)^2w^2}+\frac{1}{(2m-1)^2d^2}\right] \qquad (21)$$

Defining the function $F(s)$ as

$$F(s)=\frac{64}{\pi^2\mu\sigma}\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}\times$$

$$\frac{\frac{1}{(2n-1)^2w^2}+\frac{1}{(2m-1)^2d^2}}{s+\frac{\pi^2}{\mu\sigma}\left[\frac{(2n-1)^2}{d^2}+\frac{(2m-1)^2}{w^2}\right]} \qquad (22)$$

the expression for $H_{avg}(s)$ may be written in the form

$$H_{avg}(s)=\frac{Ni(0^+)}{rs}+\left[\frac{NI(s)}{r}-\frac{Ni(0^+)}{rs}\right]F(s) \qquad (23)$$

Equations 9 and 23 may then be combined to furnish the following single equation for $I(s)$

$$RI(s)+sLF(s)I(s)=Li(0^+)F(s) \qquad (24)$$

whence

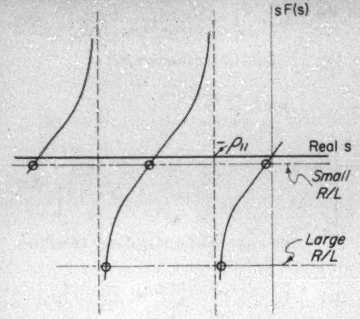
$$I(s)=\frac{Li(0^+)F(s)}{R+sLF(s)}=\frac{\frac{L}{R}i(0^+)}{\frac{sL}{R}+\frac{1}{F(s)}} \qquad (25)$$

Solution for i(t)

The expression, equation 25, for $I(s)$ has simple poles at those values of s for which

$$sF(s)=-\frac{R}{L} \qquad (26)$$

The dependence of the form of $i(t)$ both on the circuit external to the coil as well as on the characteristics of the core laminations can be demonstrated from equation 26. The inductance parameter L is dependent on the number of turns in the coil as well as the permeability, cross-sectional area, and length of the magnetic core, but it is not affected by either the conductivity of the magnetic material or the dimensions of the individual laminations. The quantity $F(s)$, on the other hand, is a function only of the dimensions of the individual laminations and the



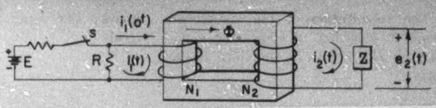


Fig. 3 (left). The variation of the roots of equation 26 with R/L ratio

Fig. 4 (above). Circuit and core arrangement for 2-mesh problem

permeability and conductivity of the magnetic material. Two extreme situations may be compared to illustrate the different effects produced on $i(t)$ by the combined effect of the circuit parameters and lamination characteristics.

$F(s)$ is a function having only poles and zeros which separate one another on the negative real axis. $F(0)$ has the value unity. The first pole is located at

$$s=-\rho_{11}=-\frac{\pi^2}{\mu\sigma}\left(\frac{1}{d^2}+\frac{1}{w^2}\right)$$

and for value of s on the negative real axis whose magnitudes are appreciably less than ρ_{11}, $F(s)$ is approximately unity. As a consequence, if R/L is small compared to ρ_{11}, the first root of equation 26 is approximately $-R/L$. Fig. 3 depicts the behavior of the function $sF(s)$ and indicates the location of the roots of equation 26 for two extreme values of the ratio R/L. The roots of the equation, shown by circles, occur at the intersections of the horizontal line displaced $-R/L$ units from the real axis with the curve representing $sF(s)$. For small values of the ratio, the poles of $I(s)$ (see equation 25) are near the zeros of $sF(s)$ whereas for large values of R/L, the poles of $I(s)$ are located in the vicinity of the poles of $sF(s)$.

An estimate of the roots of equation 26 may be made under the condition of a finite but very large value of R resulting in a high R/L ratio. In view of the Laurent expansion for $F(s)$ in the vicinity of the pole at $s=-\rho_{mn}$, it is permissible to write

$$F(s)\doteq\frac{k_{mn}}{s+\rho_{mn}} \tag{27}$$

when s is approximately equal to $-\rho_{mn}$ where k_{mn} and ρ_{mn} have the values given by equations 20 and 21. Insertion of approximation 27 in the root equation 26 yields the following approximate values for the locations of the poles of $I(s)$:

$$s=-\frac{\rho_{mn}}{1+\dfrac{k_{mn}L}{R}} \tag{28}$$

Evaluation of the residues in these poles allows the transform of $I(s)$ to be expressed as

$$I(s)\doteq Li(0^+)\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}\frac{k_{mn}\left(1+\dfrac{k_{mn}L}{R}\right)^{-1}}{s+\dfrac{\rho_{mn}}{1+\dfrac{k_{mn}L}{R}}} \tag{29}$$

In the event that R/L is not large enough for approximation 28 to be valid, $I(s)$ can be written in the general form

$$I(s)=Li(0^+)\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}\frac{k_{mn}'}{s+\rho_{mn}'} \tag{30}$$

where the ρ_{mn}' are the roots of equation 26 and k_{mn}' are the corresponding residues.

Inversion of the expression for $I(s)$ yields

$$i(t)=Li(0^+)\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}k_{mn}'\epsilon^{-\rho'_{mn}t} \tag{31}$$

for the situation where R/L has an arbitrary value and

$$i(t)\doteq Li(0^+)\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}\frac{k_{mn}\epsilon^{-\rho_{mn}t}}{1+\dfrac{k_{mn}L}{R}} \tag{32}$$

where R/L is very large. The largest value of k_{mn} occurs when $m=n=1$ and the largest value of the ratio $k_{mn}L/R$ is, therefore,

$$\frac{k_{11}L}{R}=\frac{\dfrac{64}{\pi^4}\dfrac{\pi}{\mu\sigma}\left[\dfrac{1}{w^2}+\dfrac{1}{d^2}\right]}{R/L}=\frac{64}{\pi^4}\frac{\rho_{11}}{R/L}$$

Clearly, the expression "large values of R/L" is to be interpreted as R/L being large compared to the first pole in the representation of the complex impedance function $sLF(s)$ resulting from the presence of eddy currents.

Equation 31 together with Fig. 3, which depicts the dependence of the roots ρ_{mn}' on the ratio R/L, indicates how the current $i(t)$ depends both on the circuit parameters R and L as well as the lamination characteristics. An example in which the joint dependence is more involved is considered in the next section.

Extension to 2-Mesh Problem

Fig. 4 indicates a modification of the system of Fig 1 which has just been analyzed. A coil of N_2 turns has been wound uniformly on the core and connected to the arbitrary impedance Z. It is desired to find expressions for $I_1(s)$, $I_2(s)$, and $E_2(s)$, the Laplace transforms of $i_1(t)$, $i_2(t)$, and $e_2(t)$ which are shown in the figure.

Representing the integrodifferential operator of the impedance Z by $Z(p)$ with Laplace transform $Z(s)$ (in the absence of energy storage), the equilibrium equations for the system can be written

$$Ri_1(t)+\mu AN_1\frac{dH_{\text{avg}}}{dt}=0$$

$$Z(p)i_2(t)+\mu AN_2\frac{dH_{\text{avg}}}{dt}=0 \tag{33}$$

which after transformation become

$$RI_1(s)+\mu N_1A\left[s\bar{H}_{\text{avg}}(s)-H_{\text{avg}}(0^+)\right]=0$$

$$Z(s)I_2(s)+\mu N_2A\left[s\bar{H}_{\text{avg}}(s)-H_{\text{avg}}(0^+)\right]=0 \tag{34}$$

where it is assumed there is no initial energy storage in the impedance Z. If energy is stored in Z at $t=0$, terms appropriate to the modes of energy storage must be added to the second equation 34. These two equations must be solved simultaneously with the partial differential equation 3 subject, however, to the following initial and boundary conditions:

$$H(x,y,0^+)=\frac{N_1i_1(0^+)+N_2i_2(0^+)}{r} \tag{35}$$

$$H(x,y,t)=\frac{N_1i_1(t)+N_2i_2(t)}{r}\text{ at }x=0,\ w;\quad y=0,\ d \tag{36}$$

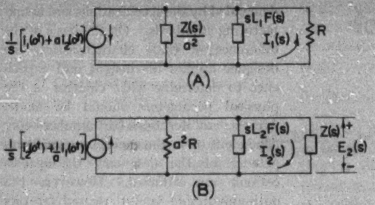

Fig. 5. Views of equivalent circuit

A—From primary (N_1) side
B—From secondary (N_2) side
a = turns ratio = N_2/N_1

By defining self- and mutual inductances as follows:

$$L_1=\frac{\mu N_1^2A}{r};\ M=\frac{\mu N_1N_2A}{r};\ L_2=\frac{\mu N_2^2A}{r}$$

and by the use of condition 35, equations 34 can be expressed as

$$RI_1(s)+\mu N_1As\bar{H}_{\text{avg}}(s)=L_1i_1(0^+)+Mi_2(0^+)$$

$$Z(s)I_2(s)+\mu N_2As\bar{H}_{\text{avg}}(s)=L_2i_2(0^+)+Mi_1(0^+)\quad(37)$$

It is necessary now to express $\bar{H}_{\text{avg}}(s)$ in terms of $I_1(s)$ and $I_2(s)$. This can be accomplished using the analysis following equation 9 with

$$\frac{Ni(0^+)}{r}$$

and

$$\frac{NI(s)}{r}$$

being replaced by

$$\frac{N_1i_1(0^+)+N_2i_2(0^+)}{r}$$

and

$$\frac{N_1I_1(s)+N_2I_2(s)}{r}$$

respectively. Referring to equation 23, the expression for $\bar{H}_{\text{avg}}(s)$ for the 2-mesh problem becomes

$$\bar{H}_{\text{avg}}(s)=\frac{N_1i_1(0^+)+N_2i_2(0^+)}{r}+\left[\frac{N_1I_1(s)+N_2I_2(s)}{r}-\frac{N_1i_1(0^+)+N_2i_2(0^+)}{rs}\right]F(s)\quad(38)$$

Equations 37 can then be written as

$$[R+sL_1F(s)]I_1(s)+sMF(s)I_2(s)=L_1F(s)i_1(0^+)+MF(s)i_2(0^+)$$

$$sMF(s)I_1(s)+[Z(s)+sI_2F(s)]I_2(s)=MF(s)i_1(0^+)+L_2F(s)i_2(0^+)\quad(39)$$

Solution of these equations gives the following expressions for the transforms of $i_1(t)$, $i_2(t)$, and $e_2(t)$:

$$I_1(s)=\frac{Z(s)F(s)[L_1i_1(0^+)+Mi_2(0^+)]}{Z(s)[R+sL_1F(s)]+RsL_2F(s)}\quad(40)$$

$$I_2(s)=\frac{RF(s)[Mi_1(0^+)+L_2i_2(0^+)]}{Z(s)[R+sL_1F(s)]+RsL_2F(s)}\quad(41)$$

$$E_2(s)=\frac{Z(s)RF(s)[Mi_1(0^+)+L_2i_2(0^+)]}{Z(s)[R+sL_1F(s)]+RsL_2F(s)}\quad(42)$$

It is clear that the pole locations in all three transforms depend not only on the external circuit impedances R and $Z(s)$, but also on the characteristics of the laminations whose properties enter through the function $F(s)$. From the equations, equivalent circuits may be determined with reference to either the primary (N_1) or secondary (N_2) side of the 2-mesh circuit. Figs. 5(A) and 5(B) illustrate the form of the equivalent circuit representation. The effect of the coils wound on the magnetic material is taken into account in circuit calculations by the elements $sL_1F(s)$ and $sL_2F(s)$. In the absence of eddy currents these elements would have the value sL_1 and sL_2.

Conclusions

As demonstrated in the specific example discussed, iterated Laplace transformations have considerable value in the solution of combined circuit-field problems In problems of this kind where partia differential equations arise whose boundary conditions contain unknowns appearing as variables in associated ordinary differential equations, the iterated transformations permit solutions to the complete problem to be obtained readily. Furthermore, in the particular problem analyzed here, the iterated transform method allowed the determination of a simple equivalent circuit representation for the physical system in a straightforward fashion.

Synopsis: The conventional procedure for designing systems with many physical parameters is discussed and the translation of this procedure into digital computer operations is considered. Although it is possible to code all of the routine design calculations for a computer, it is impossible to program the insight of the design engineer. It is shown that the determination of the physical parameters for the optimum design of a system is generally equivalent to the minimization of a function subject to constraints. The application of the method of steepest descent to minimization problems is discussed. A method for extending its use to minimization with constraints is presented.

FOR YEARS, the designer responsible for synthesizing aircraft electrical systems developed his techniques from the methods of electric machine design. By using these methods, he has developed system designs chiefly by repetitive calculation and considerable insight. The existence of systems of high caliber show how successful many designers have been. With the current trend toward larger and more complex systems, however, the designer is being requested to acquire considerably more insight than was previously required. Hence it is essential to search for more efficient system design procedures than are currently in use.

Analytic techniques are available for certain classes of design problems. For instance, methods for synthesizing linear static networks are well developed, permitting one to find the circuit parameters to meet a given set of specifications.[1] In the case of complex system designs, analytic techniques are generally not applicable and thus numerical techniques must be used. The modern digital computer offers a practical means of solving such system design problems if an efficient method for their solution is available. Considerable effort is being expended on the application of a digital computer to the design of transformers.[2] This paper describes a numerical technique which provides an approach for obtaining the optimum design for a class of nonlinear systems once the system configuration is known.

The research reported here was undertaken to study the application of digital computers specifically to the design of an aircraft alternator and its associated excitation-regulation system. However, the techniques should be applicable to many design problems in other fields as well as in electrical engineering.

Conventional Design Procedure

The design of electrical systems to meet given specifications and to have minimum weight, cost, or volume is generally carried out by a trial and error procedure. This conventional design procedure is shown in in block diagram form in Fig. 1. At the beginning of a new design, the designer makes a choice of physical parameters either by assumption or from a known design. He then compares their resulting performance characteristics with those demanded by the specifications and manufacturing standards. On the basis of the difference of these characteristics, the designer applies his insight and experience to determine what changes in the physical parameters should be made. After several iterations (the number being dependent upon the experience and competence of the designer), the specifications are satisfied. However, the optimum design is not assured by this process. Numerous other designs must be made to assure that a better system design is not overlooked. At the end of this process, the most desirable system which meets all specifications, is available.

Although the calculations of the performance parameters from assumed physical parameters may be speeded up considerably by the use of a digital computer the entire conventional design procedure is not speeded up appreciably. This is true because the decisions based upon insight would be impossible to state mathematically. However, there are procedures which may be carried out entirely on a digital computer. Such a procedure is the topic of this paper. It is to be emphasized here that the authors do not propose this as a substitute for the conventional design procedure if the calculations are to be carried out manually. This procedure should be useful only if a high-speed digital computer is available for design purposes.

Characteristics of a Design Problem

In order that design formulas applicable to a certain system be found, the "topology" of the system must be known. The meaning of "topology" is illustrated by an example in which an a-c generator comprises the system. The machine may be

SAUNDERS was Visiting Associate Professor of Electrical Engineering at M. I. T. on leave from the University of California at Berkeley, Calif., during the period of time covered by this paper.

This work was conducted by the Energy Conversion Group of the Servomechanisms Laboratory at M. I. T. and was supported, in part, by Wright Air Development Center under Contract AF 33(616)-2609.

Vol.
Pt. 1
195

an asynchronous generator or a synchronous generator. The type of rotor structure must also be specified. The fixing of such features as these are referred to in this paper as the specification of the topology of the system.

After fixing the topology of the system, design formulas may be chosen that characterize the system operation and thus provide the design relations for a particular application. The design problem is then as follows. First, the specifications on system performance must be stated in terms of performance parameters given by the design formulas. If an alternator comprises the system, one constraint on a performance parameter could be that the transient reactance be less than a specified value. Another constraint might be that the total losses of the alternator be less than a fixed amount. After determining which performance parameters are to be constrained in the design, the physical parameters which are important in meeting the specifications are then available by inspection of the design formulas.

In addition, the criterion used to define optimum must be known to complete the statement of the design problem. In the case of the design of an aircraft alternator, this criterion could be the minimization of the machine weight. In other design problems, the criterion might be to achieve the minimum cost or volume for the system. Also, the minimization of a combination of such factors might be used as the criterion.

Mathematical Representation of the Design Problem

In the previous discussion, the design problem has been treated as one of meeting given specifications and optimizing in terms of a given criterion. The topology of the system to be designed is assumed fixed. The mathematical statement of the design problem is as follows. Let the quantities $x_1, x_2, \ldots, x_m$ be the physical parameters of the system which the designer may vary. The fact that n specifications must be met may be stated as

$$\begin{aligned} &f_1(x_1, x_2, \ldots, x_m) \leq y_1 \\ &f_2(x_1, x_2, \ldots, x_m) \leq y_2 \\ &\quad \cdot \qquad \cdot \qquad \cdot \\ &\quad \cdot \qquad \cdot \qquad \cdot \\ &\quad \cdot \qquad \cdot \qquad \cdot \\ &f_n(x_1, x_2, \ldots, x_m) \leq y_n \end{aligned} \tag{1}$$

where the functions $f_1, f_2, \ldots, f_n$ are the design formulas giving performance parameters in terms of the physical parameters. The constants $y_1, y_2, \ldots, y_n$ are fixed by the specifications. The criterion for optimization may be written as the minimization of a function of the physical parameters

$$G = G(x_1, x_2, \ldots, x_m) \tag{2}$$

Thus the design problem may be stated as the minimization of a function (equation 2) in the presence of constraints (equation 1). If the functional relations of equation 1 were available in analytical form, the use of Lagrange multipliers[3] would provide a straightforward method of minimization. However, design formulas for systems usually will involve empirical functions which are not amenable to analytical treatment. For this reason and due to the usual complexity of design formulas, the Lagrange method is not too useful for design in general. The following sections present a numerical method for minimizing a function in the presence of constraints, where the constraint relations need not be given as analytical expressions in terms of the physical parameters of the system. This method is readily adaptable for use with a digital computer.

The Method of Steepest Descent

The problem of minimizing a function of several variables in the absence of constraints will be considered first. This technique is known as the method of steepest descent[4].

For purposes of illustration, consider a function, $G(x_1, x_2)$, of the two independent variables, x_1 and x_2. It is desired to minimize G with respect to x_1 and x_2; that is, find the point in the x_1x_2 plane for which $G(x_1,x_2)$ takes on the smallest value. Let P_m in Fig. 2 be the point at which $G(x_1,x_2)$ is a minimum. If one moves in any direction from P_m, the value of $G(x_1,x_2)$ must increase. Therefore, near P_m, the lines along which $G(x_1, x_2)$ is constant must be closed curves encircling P_m. Let the point P_0 be specified by initial values of the independent variables,

$$\begin{aligned} x_1 &= x_1^0 \\ x_2 &= x_2^0 \end{aligned} \tag{3}$$

The choice of these initial values will be discussed later. A new set of values for x_1 and x_2 is found by moving from P_0 in the direction that gives the largest decrease of $G(x_1, x_2)$ per unit distance travelled in the x_1x_2 plane. This is the direction of the vector gradient of $-G(x_1, x_2)$ and is a direction perpendicular to the line of constant $G(x_1,x_2)$ at P_0. Thus the values of the variables at the new point P_1 are given by:

$$\begin{aligned} x_1^1 &= x_1^0 - \lambda \left.\frac{\partial G}{\partial x_1}\right|_{x_1 = x_1^0,\, x_2 = x_2^0} \\ x_2^1 &= x_2^0 - \lambda \left.\frac{\partial G}{\partial x_2}\right|_{x_1 = x_1^0,\, x_2 = x_2^0} \end{aligned} \tag{4}$$

where λ is a positive constant. Using vector notation

$$\vec{x}^1 = \vec{x}^0 - \lambda \nabla G(x_1, x_2)\Big|_{\vec{x} = \vec{x}^0} \tag{5}$$

where

$$\nabla G = \text{gradient } G \equiv \left[\frac{\partial G}{\partial x_1}, \frac{\partial G}{\partial x_2}\right]$$

The elements, $\partial G/\partial x_1$ and $\partial G/\partial x_2$, of the matrix are the components of the vector ∇G in the x_1 and x_2 directions. It is evident that one step in the direction of the gradient will not, in general, take one to the minimum at P_m. Hence, this procedure should be repeated until some criterion is satisfied. In Fig. 2, for example, it takes six iterations to converge on P_m within the allowable error. A suitable criterion is that the change in $G(x_1,x_2)$ observed on the last step be less than some chosen value. The value of the constant λ must be controlled carefully to avoid so large a value that the solution does not converge to the point P_m. Also λ should not be so small that an excess number of iterations are required. One method of controlling λ is by observing the angle between successive evaluations of the gradient vector. If the angle is smaller than a given value, λ may be doubled; if the angle is too large, λ is halved. In addition λ is never allowed to be so large that $G(x_1,x_2)$ is increased.

This method may be extended to any number of independent variables with only the loss of the simple geometric interpretation given above.

Minimization with Constraints

The problem of minimizing a function of m variables subject to n equality constraints is considered first. That is, the

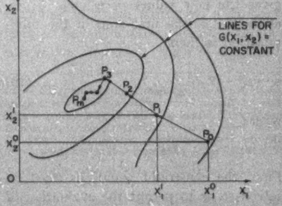

Fig. 2. Method of steepest descent

equality signs hold in equation 1. In general, only n of the variables, say $x_1, x_2, \ldots, x_n$, are constrained by equation 1. Therefore, k of the variables where $k=m-n$, may be changed so as to achieve the minimization of G. These k variables will be called $w_1, w_2, \ldots, w_k$. The problem then becomes one of minimizing $G=G(x_1, x_2, \ldots, x_n, w_1, w_2, \ldots, w_k)$ subject to the constraints

$$
\begin{aligned}
&f_1(x_1, x_2, \ldots, x_n, w_1, w_2, \ldots, w_k)=y_1\\
&\quad\vdots\\
&f_n(x_1, x_2, \ldots, x_n, w_1, w_2, \ldots, w_k)=y_n
\end{aligned}
\qquad (6)
$$

Since the variables $x_1, x_2, \ldots, x_n$ are now dependent, G is an implicit function of $w_1, w_2, \ldots, w_k$; that is,

$$G=G(w_1, w_2, \ldots, w_k) \qquad (7)$$

If this function could be obtained explicitly by elimination of $x_1, x_2, \ldots, x_n$ by the use of equation 6, the problem could be solved by the minimization procedure for the case of no constraints. However, an explicit expression for equation 7 would in general be impossible to obtain. On the other hand, it is not really necessary to have an explicit form of equation 7 to be able to apply the method of steepest descent to the problem. One needs only to evaluate the derivatives

$$
\begin{aligned}
&\left.\frac{\partial G}{\partial w_1}\right|_f \simeq \left.\frac{\Delta G}{\Delta w_1}\right|_{\substack{w_2, w_3, \ldots, w_k \text{ constant}\\ \Delta f_1=\Delta f_2=\ldots=\Delta f_n=0}}\\
&\quad\vdots\\
&\left.\frac{\partial G}{\partial w_k}\right|_f \simeq \left.\frac{\Delta G}{\Delta w_k}\right|_{\substack{w_1, w_2, \ldots, w_{k-1} \text{ constant}\\ \Delta f_1=\Delta f_2=\ldots=\Delta f_n=0}}
\end{aligned}
\qquad (8)
$$

in order to evaluate the gradient of G

$$\nabla_f G \equiv \left[\left.\frac{\partial G}{\partial w_1}\right|_f, \left.\frac{\partial G}{\partial w_2}\right|_f, \ldots, \left.\frac{\partial G}{\partial w_k}\right|_f\right] \qquad (9)$$

The partial derivatives of equation 8 are written in terms of differences to indicate the numerical technique used for their evaluation.

The equivalent of equation 5 which gives the new values of $w_1, w_2, \ldots, w_k$ at the end of the first step in the minimization is then

$$\vec{w}^1=\vec{w}^0-\lambda\nabla_f G\Big|_{\vec{w}=\vec{w}^0} \qquad (10)$$

where

$$\vec{w}=[w_1, w_2, \ldots, w_k]$$

First, the constraint equations must be solved so as to permit the evaluation of $\nabla_f G$. Let $\Delta x_{1,1}, \Delta x_{2,1}, \ldots, \Delta x_{n,1}$ be the changes in $x_1, x_2, \ldots, x_n$ respectively, necessary to keep the constraints satisfied when w_1 has been changed by a small amount Δw_1 while the other w's remain constant. These Δx's are obtained by solving the following set of linear equations in terms of Δw_1.

$$
\begin{aligned}
&-\frac{\partial f_1}{\partial w_1}\Delta w_1 \simeq \frac{\partial f_1}{\partial x_1}\Delta x_{1,1}+\frac{\partial f_1}{\partial x_2}\Delta x_{2,1}+\ldots+\frac{\partial f_1}{\partial x_n}\Delta x_{n,1}\\
&\quad\vdots\\
&-\frac{\partial f_n}{\partial w_1}\Delta w_1 \simeq \frac{\partial f_n}{\partial x_1}\Delta x_{1,1}+\frac{\partial f_n}{\partial x_2}\Delta x_{2,1}+\ldots+\frac{\partial f_n}{\partial x_n}\Delta_{n,1}
\end{aligned}
\qquad (11)
$$

Equation 11 is obtained from equation 6 by setting $\Delta f_1=\Delta f_2=\ldots\Delta f_n=0$. The partial derivatives of equation 11 are evaluated at the point $\vec{w}=\vec{w}^0$ and are constants. Therefore, the solution is of the form

$$
\begin{aligned}
&\Delta x_{1,1}\simeq\alpha_{1,1}\Delta w_1\\
&\quad\vdots\\
&\Delta x_{n,1}\simeq\alpha_{n,1}\Delta w_1
\end{aligned}
\qquad (12)
$$

where $\alpha_{1,1}, \ldots, \alpha_{n,1}$ are constants. Since by definition

$$\left.\frac{\partial G}{\partial w_1}\right|_f \equiv \lim_{\Delta w_1\to 0}\frac{\dfrac{\partial G}{\partial x_1}\Delta x_{1,1}+\ldots+\dfrac{\partial G}{\partial x_n}\Delta x_{n,1}+\dfrac{\partial G}{\partial w_1}\Delta w_1}{\Delta w_1} \qquad (13)$$

then from equation 12,

$$\left.\frac{\partial G}{\partial w_1}\right|_f \simeq \frac{\partial G}{\partial x_1}\alpha_{1,1}+\ldots+\frac{\partial G}{\partial x_n}\alpha_{n,1}+\frac{\partial G}{\partial w_1} \qquad (14)$$

In the same manner,

$$\left.\frac{\partial G}{\partial w_2}\right|_f, \ldots, \left.\frac{\partial G}{\partial w_k}\right|_f$$

may be evaluated and hence $\vec{w}^1$ is given by equation 10. However, the new values of the dependent variables $x_1{}^1, x_2{}^1, \ldots, x_n{}^1$ must be found before another step toward the minimum of G is made. Since the change in x_1 in moving from P_0 to P_1 is

$$x_1{}^1-x_1{}^0=\alpha_{1,1}(w_1{}^1-w_1{}^0)+\alpha_{1,2}(w_2{}^1-w_2{}^0)+\ldots+\alpha_{1,k}(w_k{}^1-w_k{}^0), \qquad (15)$$

$$x_1{}^1=x_1{}^0-\lambda\left[\alpha_{1,1}\left.\frac{\partial G}{\partial w_1}\right|_f+\alpha_{1,2}\left.\frac{\partial G}{\partial w_2}\right|_f+\ldots+\alpha_{1,k}\left.\frac{\partial G}{\partial w_k}\right|_f\right] \qquad (16)$$

by combining equations 10 and 15, thereby giving the value of x_1 at the new point P_1. In the same way, the values of $x_2, \ldots, x_n$ at P_1 are found. Then, the same procedure is initiated again to evaluate the next step toward the minimum, and so on until the point P_m is reached The value of λ can be controlled in a manner identical to the method used for the unconstrained case described in the previous section.

This method for minimizing a function in the presence of equality constraints is readily applicable to digital computation. The partial derivatives are approximated by the use of difference methods and the solution of the linear simultaneous equations of equation 11 may be effected by standard matrix inversion techniques.

An extension of this method, which can be used in solving a design problem when the constraints are inequalities, is as follows. (Since this paper was written J. B. Dennis has developed a general procedure for minimizing a function subject to nonlinear inequality constraints. This method will always converge to the nearest relative minimum. See reference 5.) A set of initial values of the physical parameters is chosen such that equation 1 is satisfied. Since the inequalities hold for all of the constraints, then each of the physical parameters may be changed at least a small amount without violating any of the constraint equations. Thus, in the beginning, the problem may be treated as minimization without constraints. If a minimum is obtained without ever violating any of the constraint equations, the constraints are not significant or the phrasing of the problem is inconsistent. However, if any of the constraints are significant, one of them will eventually be violated as steps toward the minimum are taken. At the point where a constraint is first violated its equal sign is assumed to hold and the problem becomes one of minimizing with one equality constraint which is treated by the procedure previously described. Thus, the number k of independent variables w is decreased by one, and the number n of dependent variables is one. As more steps are made, more of the constraint equations will be violated and their effects brought into the computation by the addition of dependent variables until the minimum is reached.

Difficulties with the Steepest Descent Method

Since the method of steepest descent described involves taking derivatives, it is basically applicable to problems for which the functions involved are continuous and have continuous derivatives. In many design problems there are both continuous variables to which any value may be assigned, and discrete variables which may only take on certain fixed values. The discrete variables can be handled with the minimization procedure in one of two ways depending on the number of values each discrete variable is allowed to assume. If there are only a small number of values that a particular discrete variable may have, then the design problem is solved by applying the minimization process once for each value of the discrete variable and noting which one gives the smallest minimum of G. If there are many possible values for the discrete variable this method becomes impractical because of computer time consumption. For these cases, one can replace the discrete variable with a continuous variable such that the necessary derivatives would be continuous and sufficiently smooth. Then the minimization could be performed resulting in a value of the continuous variable lying between two allowed values of the original discrete variable. These two values could then be tried separately and the better one chosen for the final design. These ideas can be extended to design problems involving several discrete variables.

A more serious difficulty with the steepest descent method is that the minimization problem may have several minima. The minimization procedure will find one of these minima, the exact one depending on the choice of initial values of the variables. A check can be made as to whether the true minimum had been obtained by trying several widely differing initial choices of parameter values and verifying that the same answer is obtained. Another way is to insure that the initial selection of parameter values is sufficiently close to the optimum so that there would be no difficulty. Such a set of physical parameters may be known from a previous design, or may be obtained by preliminary calculations.

Conclusions

This paper provides a numerical method (adaptable to a digital computer) for minimizing a function in the presence of constraints.

The method should prove useful in design optimization is the design problem can be expressed subject to the assumptions which follows.

1. The topology of the system is fixed.
2. Design formulas (relations between performance parameters and the physical parameters) are available.
3. The process of optimization is equivalent to the minimization of some function of the physical parameters.
4. The specifications may be expressed in terms of n constraint inequalities involving functions of the physical parameters.
5. An initial design is available which satisfied the constraint equations.
6. Only one minimum exists for the function being minimized or a sufficiently good initial design is known.

The Numerical-Graphical Method in the Design of Multiterminal Switching Circuits

A. H. SCHEINMAN
ASSOCIATE MEMBER AIEE

UP TO the present time there has been no satisfactory direct method for designing multiterminal switching circuits. A common approach is to consider each output individually and derive a 2-terminal network for it. An attempt is then made to change the form of the individual 2-terminal networks, if possible, so that combinations between paths may be facilitated. This may be done, for example, by algebraic manipulation of the switching functions describing the 2-terminal networks. Extreme care must be taken in any case so that the individual outputs remain disjunctive.

The type of multiterminal circuit generally encountered is illustrated in Fig. 1. This circuit has a multiplicity of input leads and two or more output leads. The input leads control relays which serve to provide the necessary contacts to form the paths from some common point, usually ground, to control the output leads in accordance with the circuit specifications.

Two methods are presented in this paper for designing multiterminal circuits. Both methods are based upon the numerical-graphical method[1] which will now be summarized.

In the switching algebra that appears in this paper, the following conventions are used:

0 = open circuit.
1 = closed circuit.
Addition (+) = parallel connection = or.
Multiplication = series connection = and.
An unprimed variable denotes a make contact.
A primed variable denotes a break contact.

Procedure Summarized[1]

The desired switching function can be represented by a table of combinations, each row of which represents a product term of the disjunctive canonical expansion of the function. Each of the input

variables has a binary weight associated with it depending on its position in the table. Each row can then be represented by a decimal equivalent which enables the original switching function to be conveniently specified by a series of decimal numbers.

A transfer contact of the most heavily weighted variable is then introduced. Two new functions are formed, one in series with the break contact and one in series with the make contact. The function in series with the break contact consists of all of the decimal numbers of the original function which are less than the weight of the variable introduced. The function in series with the make contact consists of the decimal numbers which are equal to or greater than the weight of the variable introduced, from each of which the weight of the variable is subtracted. The new functions are compared to see if one of the following rules may be applied:

Rule 1. Equal functions of the same variables may be combined.

Rule 2. If one of the two functions emanating from a transfer contact is a subset of the other, the element of the transfer contact in series with the subset may be short circuited. The decimal numbers in series with the other element of the transfer contact which correspond to those of the subset become "don't-care" terms.

Rule 3. If in the development of the circuit identical contact configurations appear in series with the make and break elements of the transfer contact being introduced, they may be shifted to the left of the transfer contact and combined.

Multiterminal Circuits

Two approaches to the design of multiterminal circuits will now be presented. The three rules summarized before, of the numerical-graphical method apply in the same manner as for 2-terminal circuit design.

Method 1

In this method a single decimal number identifies a product term of the canonical expansion and in addition the output lead

Fig. 5 (above). Method 1 with six relays. See Fig. 4 caption for identifications

to which a closure must be made if that combination of input variables occurs. A simple example will make this clear.

Assume a circuit with 3 inputs, X_1, X_2, and X_3, and 2 outputs, Y_1 and Y_2, such that Y_1 and Y_2 are grounded according to the following equations:

$$f(Y_1)=X_3'X_2'X_1+X_3'X_2X_1'+X_3X_2'X_1'+X_3X_2X_1$$

$$f(Y_2)=X_3'X_2'X_1'+X_3'X_2X_1+X_3X_2'X_1+X_3X_2X_1'$$

A composite table of combinations is drawn as shown in Fig. 2(A), where a 1 in an output column indicates that the output is grounded for the combination of input variables in the corresponding row. For example, the combination X_3' X_2' X_1' causes output Y_2 to be grounded, and this is indicated by the first row of the table of combinations, 00010.

The entire row is then assumed to be one binary number and is replaced by its decimal equivalent.

There is one restriction for the direct use of method *1*. For any particular combination of input variables only one output may be grounded. Taking advantage of this restriction the first output is arbitrarily given a weight of zero instead of one as it would normally be in a true binary number. This is done to make the 2-terminal circuit a special case of method *1* where the single output is given zero weight. It is of course just as valid to consider the number as a true binary and give the first output a weight of one. The former scheme will be adopted here however.

The decimal equivalents are obtained as shown in Fig. 2(A). Fig. 2(B) shows the development of the circuit, which is carried out exactly as for the 2-terminal case. The difference becomes apparent after transfers of the last variable are introduced. There will then be as many leads as there are outputs and the leads will be numbered the numbers corresponding to the weights of the outputs. In Fig. 2(B) the two output leads are numbered 0 and 1. The table of Fig. 2(A) shows that 0 is the weight of Y_1 and 1 is the weight of Y_2, thus identifying the outputs. The circuit has now been completed and we note that five transfer contacts are required.

As noted previously, if more than one output is to be grounded for any particular combination of input variables, then method *1* cannot be used directly. However, by using a bridging network across the outputs in question consisting of the common combinations of input variables, the problem can be converted to one in which method *1* can be used.

Consider as an example a circuit as shown by the table of combinations of Fig. 3(A).

$$f(Y_1)=X_3'X_2'X_1'+X_3'X_2X_1'+X_3'X_2X_1+X_3X_2'X_1'$$

$$f(Y_2)=X_3'X_2'X_1+X_3'X_2X_1'+X_3'X_2X_1+X_3X_2'X_1$$

This is shown symbolically in Fig. 3(B) where $f(Y_1)$ is shown as network *A* and $f(Y_2)$ as network *B*. Since some of the combinations of networks *A* and *B*

4	2	1			DECIMAL EQUIV. OF
X_3	X_2	X_1	Y_2	Y_1	INPUT VARIABLES
1	1	1	0	1	7
0	1	1	1	0	3
1	1	0	0	1	6
0	1	0	1	0	2
1	0	1	1	1	5
0	0	1	1	1	1

(A)

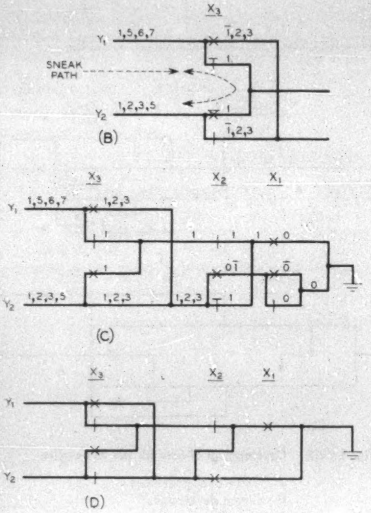

Fig. 6. Circuit development by method 2 showing sneak path

A—Table of combinations
B—Sneak path
C—Circuit development
D—Completed circuit

are common to both, method *1* cannot be used directly. If, however, networks *A* and *B* are converted to networks *C* and *D* [see Fig. 3(C)] which have no common combinations and a network *E* is added which is composed of the common combinations, then method *1* can be used to synthesize a circuit composed of the *C* and *D* networks. Network *E* is a 2-terminal network which can be designed directly. Note that the common input combinations must appear in either network *C* or *D* but not both. It is often helpful in determining whether to use any particular combination in either *C* or *D* to use a Karnaugh map.[2] The choice is made in a manner consistent with the normal use of the map, that is, to obtain the smallest number of subcubes which are as large in dimensions as possible. The circuit can now be developed as shown in Fig. 3(E).

The bridging network development is shown in Fig. 3(F). Note that any combinations which are not used in either networks *C* or *D* may be included in the bridging network as don't care combinations. The completed circuit is shown in Fig. 3(G).

METHOD 2

The second method has no restrictions in its use as does method *1* and may always be applied directly. The resulting circuits, however, are not always as efficient as those obtained by the use of method *1*.

In method *2*, only the input variables are weighted and the decimal equivalents are based on the input combinations only. Thus in Fig. 2(A), to apply method *2*, the decimal equivalents are based on the input variable combinations and X_3, X_2, and X_1 have binary weights of 4, 2, and 1 respectively. Therefore:

$$f(Y_1) = \Sigma\, 1, 2, 4, 7$$

$$f(Y_2) = \Sigma\, 0, 3, 5, 6$$

The circuit is then developed from the outputs toward the common input, which is here assumed to be ground. Interconnections are made between circuits by application of rule *1*. Fig. 2(C) shows the development of the circuit and it is noted that five transfer contacts are required as in the circuit development using method *1*. The distribution of contacts differs however.

Although the total number of contacts required in this simple example are the same when using either method *1* or *2*, this will not generally be true. Use of method *1* results in circuits that are at least as economical of contacts as method *2* and often more economical. In addition the circuit economy resulting from use of method *2* is often quite sensitive to the order of variables in the table of combinations. Method *2*, as described here, is similar to a circuit design method developed by Roginskii.[3]

Networks and Their Negatives

Occasionally a circuit is desired which has two outputs, where one of the outputs is the negative of the other. This class of circuit can always be designed by method *1*. A typical example is shown in Fig. 4 which can readily be followed.

A Six-Relay Circuit

A six-relay circuit with two outputs is illustated in Fig. 5. This example is included to show how routinely such a problem can be designed by the numerical-graphical method. The example is also intended to illustrate the application of all three rules.

Extraneous Circuit Closures

Extraneous circuit closures or "sneak paths" may inadvertently be developed by application of rule *2* followed by rule *1*. If this should occur, rule *2* should not be applied.

Fig. 6 illustrates the development of a sneak path using method *2*. When using method *2*, rule *2* must be applied with caution since the sneak path may not appear immediately, but only after contacts of subsequent variables are introduced. It is usually easier to detect sneak paths when using method *1* than with method *2*. Note that sneak paths can never be developed if rule *2* is not applied.

Use of Other Codes

In this paper the decimal code was used exclusively. However, there is no reason to preclude the use of other codes since the codes are used as a convenient means of specifying circuit transmissions and the particular code used is incidental to the method. A very useful code, for example, is the octal code. This has an advantage over the decimal in the ease of translation from the binary numbers which specify the circuit transmission to the equivalent octal numbers. All the rules governing the application of the numerical-graphical method apply directly regardless of the code used.

Conclusions

The numerical-graphical method enables a designer to develop economical multiterminal circuits in a fairly simple and straightforward manner. Usually the circuit arrangements are at least as economical as those obtained by other methods.

Most circuit designers generally do not use any of the currently available design tools. This is probably true because practical problems usually involve large numbers of variables and present methods rapidly exceed the limits of practicability as the number of variables involved increases.

The numerical-graphical method may not be a panacea, but by its use a designer is at least able to approach the problem of designing large circuits in an orderly fashion.

Recommended Symbols for Magnetic Amplifier Papers—A Report

AIEE COMMITTEE REPORT

FOR THE PURPOSE of increasing the uniformity of symbols in magnetic amplifier papers, Mr. Harold W. Lord, chairman of the AIEE Magnetic Amplifier Committee, asked the Theory Subcommittee to prepare a list of recommended symbols.

The members of the Theory Subcommittee were invited to make proposals, which were collected and circulated among the Theory Subcommittee members for comments. While some members were in complete agreement with the first proposal, others offered changes, and as a result, the original list was revised. Then, this revised list was circulated, but not only among the members of the Theory Subcommittee, but also among the members of the Main Magnetic Amplifier Committee for further comments. Of the letters received owing to this last circulation, only one letter expressed a wish for further changes. The proposals contained in this letter, however, were certain to cause considerable opposition among the members of the Theory Subcommittee, and hence, no further changes were made on the revised list of recommended symbols.

The following contains the revised list of recommended symbols for magnetic amplifier papers, obtained under the circumstances described in the foregoing.

Previously Standardized Symbols

The basis for the recommended symbols is formed by the symbols shown in Appendix IV of AIEE's Author's Guide page 19, also known as the American Standard Letter Symbols for Electrical Quantities.[1] These symbols are shown in Table A for scalars (designations for phasors are bold italics, bold roman for vectors).

Table A

A1.	Admittance	$\boldsymbol{Y}$
A2.	Angular frequency (angular velocity)	ω
A3.	Capacitance	C
A4.	Capacitivity (dielectric constant)	ϵ
A5.	Conductance	G
A6.	Conductivity	γ
A7.	Current	I
A8.	Damping constant	δ
A9.	Displacement flux	Ψ
A10.	Efficiency	η
A11.	Elastance	S
A12.	Electric displacement	$\mathbf{D}$
A13.	Electric intensity	$\mathbf{E}$
A14.	Electromotive force	E
A15.	Energy, work	W
A16.	Force	$\mathbf{F}$
A17.	Frequency	f
A18.	Impedance	$\boldsymbol{Z}$
A19.	Inductance	L
A20.	Magnetic intensity	$\mathbf{K}$
A21.	Magnetic flux	Φ
A22.	Magnetic induction	$\mathbf{B}$
A23.	Magnetic vector potential	$\mathbf{A}$
A24.	Magnetomotive force	$\mathcal{F}$
A25.	Mutual inductance	L_m
A26.	Number of conductors or turns	N
A27.	Permeability	μ
A28.	Permeance	$\mathcal{P}$
A29.	Period	T
A30.	Phase angle	φ
A31.	Potential	V
A32.	Power	P
A33.	Power factor	$\boldsymbol{F_p}$
A34.	Electric charge (quantity of electricity)	Q
A35.	Reactance	X
A36.	Resistance	R
A37.	Resistivity	ρ
A38.	Reluctance	$\mathcal{R}$
A39.	Reluctivity	ν
A40.	Rotational frequency	n
A41.	Susceptance	B
A42.	Time constant	τ
A43.	Velocity of light	c
A44.	Wavelength	λ

Additional Symbols

In addition to the 44 symbols listed in Table A, the symbols in Table B are recommended.

Table B

B1.	Cross section	A
B2.	Ampere-turns (see note B2)	AT
B3.	Dynamic power gain (see note B3)	D_P
B4.	Gain (response Function)	$g(t)$, $G(s)$, $G(j\omega)$, $G^*(s)$
B5.	Gain (invariant)	K
B6.	Form factor	k_f
B7.	Length	ℓ
B8.	Current density	J
B9.	Saturable reactor (see note B9)	SR
B10.	Loss, energy, e.g., core loss/cycle	W
B11.	Angle at which the core saturates	α

Note B2. Ampere-Turns—AT

AT can be used as a unit of magnetomotive force, but should not be used as a symbol for magnetomotive force for which the symbol $\mathcal{F}$ has been reserved, see A24 Table A.

Paper 59-173, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted August 18, 1958; made available for printing December 2, 1958.

The personnel of the Theory Subcommittee of the AIEE Magnetic Amplifiers Committee are: H. F. Storm, *chairman*, R. C. Barker, Paul P. Biringer, H. C. Bourne, Jr., A. Boyajian, L. A. Finzi, F. J. Friedlaender, H. L. Goldstein, Alexander Kusko, H. W. Lord, B. W. Manteuffel, R. A. Ramey, R. W. Roberts, A. B. Rosenstein, T. G. Wilson.

Note B3. Dynamic Power Gain—D_P

The term "dynamic power gain" has been in use in Europe for quite a number of years to designate the power gain per second. The symbol in use is D. Since the magnetic amplifier also displays a dynamic voltage gain, and perhaps others, the subscript P was added, resulting in the proposed symbol D_P. In this country there is also the term "figure of merit" in use to express the power gain per second; however, the term dynamic power gain is more specific than figure of merit, which may relate to many meritorious relations.

Note B9. Saturable Reactor—SR

The abbreviation *SR* is analogous to such widely accepted abbreviations as *CT* for current transformer or *PT* for potential transformer.

Lower Case Subscripts

The following lower case subscripts are recommended:

Table C

C1.	Average (see note C1)	*a*, 0
C2.	Coercive	*c*
C3.	Effective (see note C3)	*e*
C4.	Intrinsic	*i*
C5.	Maximum (peak)	*m*
C6.	Residual induction	*r*
C7.	Saturation	*s*
C8.	Reverse rectifier (voltage or current)	*r*
C9.	Forward rectifier (voltage or current)	*f*

Note C1. Average Values

There are two basic kinds of average values in magnetic amplifier work. Let us consider first the following:

$$E_0=\frac{1}{T}\int_0^T e(t)dt \qquad (1)$$

E_0 represents the average of the variable $e(t)$ when averaged over the entire period T, such as when determining the average value of the voltage of a rectifier. The term E_0 is identical with the zero-frequency term of a Fourier analysis of the variable $e(t)$, and hence should be designated by a subscript of 0. E_0 should be pronounced "E subzero."

Another type of average is expressed by the following:

$$E_a=\frac{2}{T}\int_0^{T/2} e(t)dt \qquad (2)$$

E_a represents the average of the variable $e(t)$ when averaged over only one-half of the period, such as when determining the flux swing in one core of a single-phase full-wave magnetic amplifier. This average value is called half-period or half-cycle average, and it is a quantity which is of dominating importance in magnetic amplifier work.

The half-period average should be designated by a subscript of a as shown in E_a. However, since the half-period average is so predominant, the continuous usage of a subscript may be considered cumbersome, in which case the option is offered of not using any subscript at all when designating the half-period average value in magnetic amplifier papers. In polyphase magnetic amplifiers, the integration is carried out over a fraction of the period, different from one-half. The designation for this average is for instance one-third-cycle average, or one-sixth-cycle average, etc., and the notation remains E_a or E.

Note C3. Effective Values

A subscript *e* should be used in magnetic amplifier papers to denote effective (root-mean-square) values in order to avoid confusion between average and effective values.

Upper-Case Subscripts

The following upper-case subscripts are recommended:

Table D

D1.	Ampere-turn	*AT*
D2.	Bias	*B*
D3.	Control	*C*
D4.	Copper	Cu
D5.	Voltage	*E*
D6.	Feedback	*F*
D7.	Iron	Fe
D8.	Gate	*G*
D9.	Current	*I*
D10.	Load	*L*
D11.	Output	*O*
D12.	Power	*P*
D13.	Resistance	*R*
D14.	Rectifier	REC
D15.	Excitation	EXC
D16.	Window	*W*

Upper-Case Versus Lower-Case Letters

There is a note to the American Standard Letter Symbols which states that lower-case letters should be used for instantaneous values. Some of the Subcommittee members made strenuous objections against this rule, when it came to b, h, and f for the instantaneous values of flux density, magnetic intensity, and magnetomotive force, at least for the time being. In cases where the instantaneous character of the variable requires emphasis, it should be designated by $B(t)$, $H(t)$, $F(t)$. No objections were raised against using lower case ϕ and ψ for the instantaneous values of magnetic flux, and of magnetic-flux linkage, respectively, and hence lower-case letters should be used for these two quantities.

◆

Discussion

G. E. Lynn (Westinghouse Electric Corporation, Baltimore, Md.): The work of the Theory Subcommittee in preparing this paper has resulted in a most welcome addition to the lengthening list of standards available in the field of magnetic amplifiers. It is a foregone conclusion that the symbols presented in the paper represent numerous compromises within the Subcommittee and it is probably not to be expected that the results will be equally palatable to all practitioners in the magnetic amplifier field. With an appreciation of these facts, disagreements stemming principally from personal prejudices or preferences should not be submitted for discussion.

It would seem, however, that some specific symbols proposed violate, in some degree, the aims of standardization. It would not appear wise, for example, to standardize a symbol which differs from accepted standards in other fields merely on the basis of expediency or because of established precedent only in magnetic amplifier literature. Particularly, the proposal that the symbols denoting an rms value carry a subscript while those denoting average values need not seems at variance with standard symbols in other electrical fields. A review of recent magnetic amplifier literature indicates that almost all quantities involving average values already carry a subscript and are defined as average values in the accompanying list of symbols. It would appear that if, in a particular paper or book, an author should feel that use of a subscript for average values would work undue hardship, the author is at liberty to use a nonstandard symbol and define it properly himself. This would eliminate possible confusion arising from someone outside the magnetic amplifier field attempting to understand a paper without first consulting the magnetic amplifier standard symbols list.

In addition to the change suggested in the foregoing, some additions to the list of standard symbols would be desirable. For those who prefer a figure of merit based on power gain per cycle to the dynamic power gain defined in the paper, an adequate symbol should be defined. Also, since control winding refers to any winding other than the gate winding, the use of E_c for the signal voltage can lead to confusion. It is suggested that the capital subscript S be added to Table D of the paper to stand for "signal."

Vol.
Pt. 1
195

H. F. Storm: As the title of the paper indicates the symbols listed therein are merely "recommended" for use. This means that an author fully retains his freedom of choosing symbols according to his wishes.

Mr. Lynn's specific proposals will be submitted to the Theory Subcommittee of the AIEE Magnetic Amplifiers Committee, when amendments and additions will be considered. However, it has been the consensus of the Theory Subcommittee to try the present set of symbols for one year, before introducing changes and additions.

The interest displayed by Mr. Lynn is appreciated very much. Even after the official deadline for formal discussions of the recommended symbols has been passed, members of the Institute are encouraged to further discussions of this matter with the chairman of the Theory Subcommittee.

Observation of Transients in the Series-Connected Saturable Reactor With High-Impedance Control Source

H. L. GOLDSTEIN
ASSOCIATE MEMBER AIEE

IN A SERIES-CONNECTED saturable reactor working in the proportional mode with its control winding fed by a direct current from a high impedance source, the gate current as a function of time has a rectangular shape and its amplitude, in ampere turns, is equal to the magnitude of the control current.[1] Full-wave rectification of the gate current yields a direct current closely proportional to the control current, regardless of changes in line voltage, frequency, and load resistance. Hence the name d-c transformer. This relation holds in general even under transient conditions. For instance, the gate current follows changes in the control current instantaneously and a ripple component in the control current is reproduced faithfully in the gate current even when its frequency is higher than that of the power source.[2]

An extension of Storm's analysis, however, will show that the circuit can be temporarily thrown out of its proportional mode by a transient. Transients are introduced in this investigation by short circuiting the load resistor or removing a short circuit from it at a predetermined instant of the cycle. During the transient, the waveforms of the gate current and load voltage are observed on a scope and the phase angle of the gate current in each cycle is recorded.

Theory

Circuit in Proportional Mode

The circuit under investigation is shown in Fig. 1. Two identical coils, each with the ideal magnetic characteristic shown in Fig. 2, have their control windings connected in series to a d-c source and in series with a large impedance Z, which reduces alternating currents to a small magnitude compared to that of the d-c I_C. The gate windings are connected to a source of sinusoidal voltage $e=E_m \sin \omega t$ (supply voltage), in series with the load resistance R. The relative polarities of the windings are indicated by dots. In the proportional mode of operation, always one of the coils is saturated and the other unsaturated. The gate curent i_G has a rectangular waveshape (Fig. 3), and the unsaturated coil, in which control and gate ampere-turns cancel, takes up the difference between supply voltage and load voltage $i_G R$. Between two polarity changes of the gate current $\omega t=\alpha_1$ and $\omega t=\pi+\alpha_2$, the operating point on the magnetic characteristic of the unsaturated coil moves from the knee into the unsaturated region and back again. The over-all flux swing is zero and the two shaded areas in Fig. 3, consequently, are equal.[1,3,4] This lead to the relation

$$\int_{\alpha_1}^{\pi+\alpha_2} (E_m \sin \omega t - i_G R) d\omega t = 0$$

$$\cos \alpha_1 + \cos \alpha_2 = \frac{I_G R}{E_m} (\pi + \alpha_2 - \alpha_1) \quad (1)$$

I_G = amplitude of gate current

Similarly

$$\cos \alpha_2 + \cos \alpha_3 = \frac{I_G R}{E_m} (\pi + \alpha_3 - \alpha_2) \quad (2)$$

This allows to compute the value of the phase angle (The term "phase angle" of the rectangular current is used here to designate the instant when the current changes polarity.) when that of the previous half-cycle is known. In the steady state

$$\alpha_1 = \alpha_2 = \alpha_\infty$$

and

$$\cos \alpha_\infty = \frac{\pi}{2} \frac{I_G R}{E_m} \quad (3)$$

Under steady-state conditions, the smallest value for α_∞ in the proportional mode is 32.5 degrees; in this case the edge of the $i_G R$ wave coincides with the supply voltage wave.[1] The highest value is 90 degrees, for $I_G R = 0$.

From inspection of equation 1 it follows that when $\alpha_1 < \alpha_\infty$, then $\alpha_2 > \alpha_\infty$. This in turn leads to $\alpha_3 < \alpha_\infty$ (from equation 2). By subtracting equation 2 from equation 1 we obtain

$$\cos \alpha_1 - \cos \alpha_3 = \frac{I_G R}{E_m} (2\alpha_2 - \alpha_1 - \alpha_3) > 0 \quad (4)$$

that is $\alpha_3 > \alpha_1$. This shows that the phase angle asymptotically approaches the steady-state value during a transient. The rate at which the return to steady

∞	85	

state takes place (amount of damping) is determined for given values of I_G and E_m by the magnitude of R.

Even for low values of R (low damping) deviations of the circuit from the assumed ideal conditions do not introduce any additional damping. This can be seen in the following way. Integrating the gate voltage from α_1 to α_3 leads to

$$\int_{\alpha_1}^{\alpha_3} E_m \sin \omega t \, d\omega t = E_m(\cos \alpha_1 - \cos \alpha_3) = I_G R(2\alpha_2 - \alpha_1 - \alpha_3) \quad (5)$$

The physical meaning of this equation is that the average of the supply voltage taken over a full cycle of the load current is different from zero when there is any damping ($\alpha_1 \neq \alpha_3$). Loosely speaking, the supply voltage has a direct component in this time interval. Since the average voltage across the coils in that time is zero, this direct voltage has to appear across the load, namely as the voltage drop caused by the direct component of the unsymmetrical gate current. Deviations of the circuit from the postulated ideal conditions will result in deviations of the current wave from its ideal rectangular shape. As long as they are small compared to the magnitude of the gate current, their contribution to the damping can be neglected. This explains the good agreement between measured and computed values in Table I.

Deviations from Proportional Mode

Two special cases will illustrate now how the circuit can deviate from its

Jump of Load Voltage from Finite Value to Zero

The voltage across the load is assumed to have some finite value, with the steady-state phase angle α_∞ given by equation 3. At $\omega t=\alpha_\infty$, when the gate current changes polarity, we short circuit the load and thus let I_GR drop to zero; see Fig. 4. The unsaturated coil must now absorb the full gate voltage starting from this moment, that is, earlier than under steady-state conditions with a short-circuited load. Unless the coil is designed with sufficient margin, with respect to the voltage, it will reach saturation before the end of the half-cycle. The full line voltage then will be applied to the gate circuit, resulting in a high peak of the gate current, which under actual conditions is now limited only by winding resistance and saturated inductance of the coils. After the current peak shown in Fig. 4, the current will return to its correct value when the gate voltage reverses polarity at $\omega t=\pi$. The coil is now unsaturated again and its operating point on the magnetic characteristic moves back to the other knee which it reaches at $\omega t=\pi+\alpha_2$. Here the load current changes polarity. When the amplitude of the supply voltage has its highest value consistent with the proportional mode $\alpha_2=\pi/2$. For lower values of gate voltage $\alpha_2>\pi/2$. α_2 will always be smaller than π, since the line voltage applied during a part of the cycle only was able to saturate one coil, which was the very reason for the current peak to appear. This shows that the circuit is now back to its proportional mode.

Jump of Load Voltage from Zero to Full Value

Next we assume I_GR was zero (load resistance short circuited), with the phase shift between line voltage and load current equal to $\pi/2$. At $\omega t=\pi/2$, when the load current changes polarity, we let I_GR jump to its full value; see Fig. 5. Since fewer volt-seconds are absorbed now by the unsaturated coil then under steady-state conditions, the current will reverse polarity earlier, possibly at a time when the supply voltage is not yet high enough to sustain the voltage across the load. The leading edge of the following current wave thus will be rounded off. After that, in most practical cases, the current resumes its rectangular shape again (see the appendix), with its phase gradually approaching the steady-state value as discussed before.

No Transient

The circuit can be switched from one steady-state condition to another without introducing any transient phenomenon by suitably choosing the switching moment $\omega t=\beta$. The conditions for that are (see Fig. 6)

$$\int_{\alpha_1}^{\beta}(E_m\sin\omega t-I_GR_1)d\omega t+\int_{\beta}^{\pi+\alpha_2}(E_m\sin\omega t-I_GR_2)d\omega t=0 \quad (6)$$

In addition, since α_1 and α_2 are steady-state phase angles

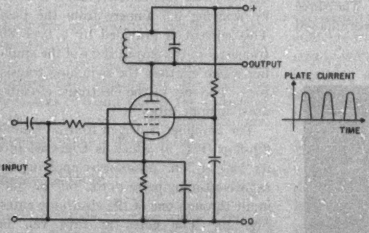

Fig. 13 (above). Frequency multiplier

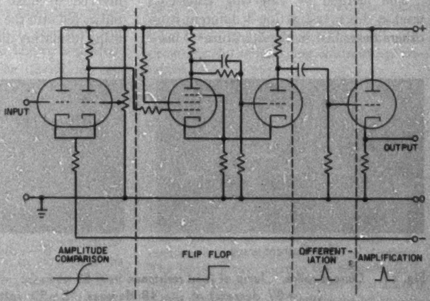

Fig. 14 (right). Pulse generator

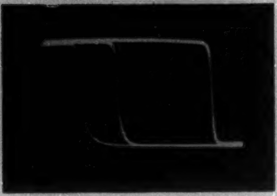

Fig. 15. Rounded edge of current wave. Jump of load resistance from 1.5 ohms (α_∞ = 87 degrees) to 25 ohms (α_∞ = 33 degrees) at ωt = 87 degrees. E = 40 volts (rms)

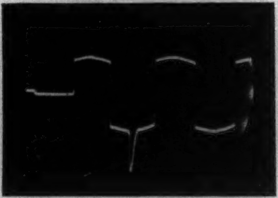

Fig. 16. Voltage spike in negative half-cycle. Jump of load resistance form 1.5 ohms (α_∞ = 87 degrees) to 12 ohms (α_∞ = 73 degrees) at ωt = 87 degrees. E = 40 volts (rms)

$$\cos\alpha_1 = \frac{\pi}{2}\,\frac{I_G R_1}{E_m} \text{ and } \cos\alpha_2 = \frac{\pi}{2}\,\frac{I_G R_2}{E_m} \qquad (7)$$

This allows to compute β. From equations 6 and 7 results

$$E_m(\cos\alpha_1 + \cos\alpha_2) = I_G R_1(\beta - \alpha_1) + I_G R_2(\pi + \alpha_2 - \beta) = \frac{\pi}{2}\,(I_G R_1 + I_G R_2)$$

$$\beta = \frac{R_1(\pi/2 + \alpha_1) - R_2(\pi/2 + \alpha_2)}{R_1 - R_2} \qquad (8)$$

Measurements

The method of observing transients used in this investigation is different from others described in the literature[5-8] insofar as the switching which starts the transient is done at a moment of the cycle predetermined to about one electrical degree. In addition, the phase angle of the gate current is recorded for every cycle of the transient to an accuracy of about one electrical degree of the 60-cps (cycles per seconds) supply voltage.

BLOCK DIAGRAM

Fig. 7 shows a block diagram of the testing setup. Transients are initiated by short-circuiting the load resistor or removing a short circuit from it with an electronic switch. The instant of the cycle when the switch is actuated is determined by a periodic negative timing pulse which can be shifted over one full cycle of the supply voltage. The waveform of the gate current is observed by connecting the *Y*-input of scope *2*, which works with linear sweep, across the small resistor R_1 (= 0.5 ohm) in the gate circuit. In addition, the voltage across the load is observed.

Scope *1*, which measures the phase of the gate current, works with a circular sweep of 240 cps so that one revolution of the beam corresponds to 90 electrical degrees of the 60-cps supply voltage. The instant to be observed is marked on the scope by applying a positive pulse to its *Z* input. The pulse is given out by a pulser circuit at the moment when the voltage applied to its inputs goes through zero in the positive direction. Pulser *1* is connected either to the 0.5-ohm resistor to monitor the gate current, or to the supply voltage to determine the origin of the time scale (zero phase shift). Pulser *2*, which is fed from a voltage of 4,320 cps derived from a frequency multiplier, provides time markers spaced 5 electrical degrees apart. The phase shifter at the input of the frequency multiplier allows to align one time marker with the origin of the time scale. To determine the switching instant, the timing pulse is applied to the scope after passing it through a phase inverter to make it positive. The three pulses fed into the scope are superimposed using insulating diodes.

DETAILS OF CIRCUITRY

More details of the circuit under test and the electronic switch are shown in Fig. 8. The data of the reactors and inductors are given in Table II. The a-c component in the control current is about 6 ma (milliamperes) 3%, the exciting current of the reactors in the unsaturated region about 10 ma (less than 1% of the gate current). With a maximum load resistance of 25 ohms, and a gate current amplitude of 1.2 amperes, the maximum amplitude of the load voltage is 30 volts. The load resistor is short-circuited with a *2N174* transistor operated as a switch.[9,10] The latter is kept open, "off" by applying +32 volts between base and emitter, and it is closed by drawing 0.3 ampere from the base. This current is provided by a type *H6* transistor in the output stage of the amplifier which controls the switching transistor. The rest of the electronic circuitry uses vacuum tubes.[11]

The amplifier is driven from a bistable flip-flop (Fig. 9) which is triggered into its "on" or "off" position by applying the negative timing pulse to its "on" or "off" input through one of the electronic gates, Fig. 10. The gates in turn can be controlled in two ways. For visual observations on the scope where it is desired to repeat a transient over and over again, an astable flip-flop (Fig. 11) alternates in

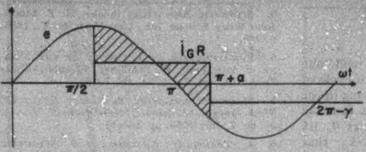

Fig. 20. Rectangular current wave after removing short circuit from load

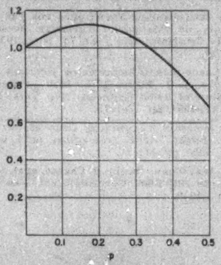

Fig. 21. Ratio of volt-time area absorbed by coil in negative half-cycle of Fig. 20, to highest value occurring in steady state

closing one or the other gate at a low rate. For taking pictures, a single transient is started with a manually operated switch which overrides the astable flip-flop. The timing pulse is taken out of a dynamic voltage tracer made by Hamner Electronics Corporation, Princeton, New Jersey. The delay between timing pulse and closing or opening of the electronic switch (3/4 or 2 electrical degrees, respectively), was considered when setting the timing pulse in the measurements.

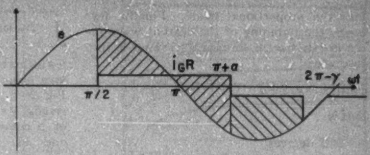
The circular sweep is obtained by applying two voltages 90 degrees out of phase to the horizontal and vertical inputs, respectively, of scope *1*, see Fig. 12. The 240 cps for the circular sweep are derived from a frequency multiplier (Fig. 13) which uses an overdriven penthode and a resonant circuit tuned to the desired harmonic of the distorted plate current. Further multiplication of the 240 cps by factors of 6 and 3 gives the voltage of 4,320 cps required for the time markers. A pulser circuit is shown in Fig. 14.

Measurements

Jump of Load Voltage from Zero to Full Value

Fig. 15 is a picture of the current wave during the transient shown in Fig. 5. Because of winding resistance of the coils and the current sensing resistor of 0.5 ohm, there is still a finite load resistance of about 1.5 ohms left in the load circuit when the transistor is short-circuited. At the right of the picture is the trace before the transient ($\alpha=87$ degrees), in the middle the steady-state condition after switching ($\alpha=33$ degrees) and to the left at $\alpha=16$ degrees the trace immediately after the switching, with the edge rounded off as predicted by theory.

Fig. 22 (right). Voltage spike in neagtive half-cycle



The load voltage spike occurring in the negative half-cycle under the conditions described in the appendix is shown in Fig. 16.

Jump of Load Voltage from Finite Value to Zero

The current spike resulting when the load is short-circuited is shown in Fig. 17(A) (compare Fig. 4). The load voltage (Fig. 17(B)) which is very low in the short-circuited condition, has also a spike because the transistor is not saturated enough to sustain a very-high-load current. Starting with the next half-cycle the current wave essentially is back to its rectangular shape.

Transient of Phase Angle in the Proportional Mode

The change of the phase angle was measured during a transient when the circuit stayed in its proportional mode. The operating conditions are given in Fig. 18 which shows a picture of the scope display. Column 1 of Table I lists the measured values for α, as taken from Fig. 18. The zero point of the time scale is indicated on the photo by a white line. In the second column of the table are values computed with equation 1, assuming the steady state values of α before and after switching as given. The deviations are smaller than 1 degree and therefore within the accuracy of measurement.

No Transient

Under the same circuit conditions as used to obtain Fig. 17, the load was short-circuited at such a moment that no transient resulted at all. The value found experimentally for the proper switching instant, $\omega t=133$ degrees, is very close to the one predicted by theory. (133.5 degrees, from data in Fig. 19 using equation 8.) Fig. 19 shows the load voltage wave under these conditions.

Conclusion

A saturable reactor with high-impedance control source, operating in its proportional mode where gate ampere-turns equal control ampere-turns, can be thrown out of this mode through a transient caused by a sudden change in operating conditions. In the experiments described here, transients are introduced by short-circuiting the load resistance or removing a short circuit from it. The deviation from the proportional behavior which results in a rounding of the normally rectangular gate current wave or a current and voltage spike, occurs only during one cycle after start of the transient. After that the circuit returns to its proportional mode. The phase of the gate current after a transient in general assumes its corresponding new value only gradually with the amount of damping (equals rate of return to steady state) determined by the magnitude of the load resistance in the new condition. By suitably choosing the switching instant, the circuit can be moved immediately from one steady state to another without any transient. Experimental and theoretical results agree within the accuracy of measurement.

Appendix

The course of the transient shown in Fig. 5 depends on the magnitude of the quantity $p=I_GR/E_m$. The maximum value possible for p in the proportional mode is 0.536 ($=\sin 32.5$ degrees); the minimum 0. From Fig. 5 the following relations are obtained

$$\int_{\pi/2}^{\pi+\alpha}(E_m \sin \omega t-I_GR)d\omega t=0$$

$$\cos \alpha=p(\pi/2+\alpha) \tag{9}$$

$$\sin \gamma=p \tag{10}$$

For $p=0.536$, $\alpha=13.7$ degrees and $\gamma=32.5$ degrees; the latter is the steady-state phase angle for the new condition. When p decreases α will increase and γ decrease. The latter means that in the negative half-cycle the unsaturated coil will now absorb more voltage seconds then required to sustain the proportional mode. Finally, for $\alpha=\gamma$, the rounding of the current wave in the negative cycle disappears. That is the case when

$$\cot\text{an}\ \alpha=\pi/2+\alpha$$

that is

$$\alpha=26.3 \text{ degrees}$$

and

$$p=0.443$$

A further decrease in p produces the current waveform shown in Fig. 20. The volt-seconds absorbed by the unsaturated coil in the negative half-cycle now are in proportion to

$$\int_{\alpha}^{\pi-\gamma}(E_m \sin \omega t-I_GR)d\omega t$$

$$=E_m[\cos\alpha+\cos\gamma-p(\pi-\alpha-\gamma)]=E_mf(p) \quad (11)$$

The highest volt-time area one coil must absorb in the steady state is in proportion to

$$\int_{\pi/2}^{\pi}E_m \sin \omega t\, d\omega t=E_m$$

$f(p)$, therefore, is the ratio of the volt-time area absorbed in the negative half-cycle of Fig. 20 to the highest value occurring in the steady state. Fig. 21 shows f as function of p computed by using equations 9, 10, and 11. For $0<p<0.33$, $f(p)>1$; that means in this range the unsaturated coil may reach the other knee of its magnetic characteristic so that the full gate voltage appears across the load; (see Fig. 22). However, a margin of about 12% in the voltage absorbing capacity of the coils would be sufficient to prevent this phenomenon.

Graphical Analysis of Full-Wave Magnetic Amplifier Control Characteristics Affected by Control-Circuit Resistance

K. MURAKAMI
NONMEMBER AIEE

T. KIKUCHI
ASSOCIATE MEMBER AIEE

SEVERAL PAPERS have been published on the correlation between the control characteristics of magnetic amplifiers and the magnetization characteristics of magnetic cores.[1–5] However, the approaches hitherto inaugurated on this subject of great importance have failed in elucidating the problem concerning the effect of control-circuit resistance (CCR) on the control characteristics of full-wave magnetic amplifiers, because of the lack of an appropriate understanding of the dynamic loop of the reactor core. In the case of the highly oriented magnetic core with rectangular hysteresis loop, the control-magnetization curve (CMC)[6,7] coincides very well with the flux-control characteristics produced by direct-voltage reset.[8,9] This experimental fact enables us to interpret CMC as the relation between the rate of flux change and the instantaneous magnetizing current.

By applying this interpretation and using the method of graphical analysis, the authors have succeeded in solving this problem. The results obtained by the analysis present a very good coincidence with the experimental data.

Experimental Study

As a preliminary to the graphical analysis of the problem, flux-control characteristics of the full-wave magnetic amplifier are measured experimentally at various values of the CCR. A flux-control characteristic is a relation between the average control current and the average induced electromotive force (emf) which is proportional to the amount of reset flux. In order to avoid the effects of a semiconductor rectifier in the gate circuits, and to realize the ideal rectifier condition, mechanical vibrating synchronous contacts are utilized.[8,9] For the reactor core, matched cores of a grain-oriented 50% iron and nickel magnetic material with an almost rectangular hysteresis loop are used.

The experimental circuit is shown in Fig. 1, where the tertiary winding, N_v, and an average sensitive d-c voltmeter together with the synchronous vibrating contacts, C_2, are adopted to measure the amount of flux reset, $\Delta\phi$, during the re-

setting half-cycle of the core.[7] Fig. 2 explains the relation between the output current, I_L, the rate of flux change of the core, $\Delta\phi/dt$, and the rectified voltage applied to the d-c voltmeter, of which the average value is E_g. Then the following relation is satisfied:

$$E_g = fN_g\Delta\phi \tag{1}$$

where f is the frequency of a-c supply voltage. The measured flux-control characteristics are shown in Fig. 3, taking various values of the CCR as a parameter. Corresponding to Fig. 3, the control characteristics of the full-wave magnetic amplifier are shown in Fig. 4. If the average value of output voltage is represented by V_L, its maximum value by V_{Lm}, the number of output winding by N_L, its resistance by R_G, and the load resistance by R_L, then there exists the following relation:

$$V_L = (V_{Lm} - 2fN_L\Delta\phi)R_L/(R_L + R_G) \tag{2}$$

In Fig. 3, the flux-control characteristics for the case of negligibly small CCR cannot be obtained by direct measurement because of the finite value of control-winding resistance. To find it, therefore, the graphical method in Fig. 5 is used. In the figure, the relation between the CCR and the average control current is plotted,

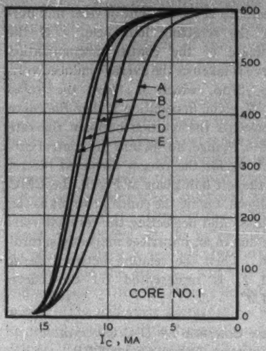

Fig. 4. Control characteristics of full-wave magnetic amplifier. Curves A through E correspond to curves B through F of Fig. 3

taking several values of flux resetting as a parameter. By extrapolating the curves to the side of zero CCR, their intersecting points with the ordinate are obtained which show the control current for the extremely low CCR. Curve *A* in Fig. 3 is thus obtained. For very large CCR, curve *G* of Fig. 3 approaches the control magnetization curve.

Fig. 6 shows the waveforms of induced voltage in magnetic-reactor cores for several values of CCR, their flux resetting level being kept constant.

From the induced voltage waveforms in Fig. 6, it is concluded that the core is reset by almost constant rectangular voltage in the case high CCR. When its resistance is low, the core is reset by the feedback voltage from the other core. For the intermediate value of CCR, both the d-c control voltage and the feedback voltage are effective and the resultant impressed voltage of the reactor winding can be assumed to take the waveform shown in Fig. 7, of which S_1 is due to the d-c control voltage and S_2 to the feedback voltage from the other reactor core.

Graphical Analysis

In this section, starting with the CMC, the method to obtain graphically the flux-control characteristics will be described, and its coincidence with the experimental result demonstrated.

INTERPRETATION OF CMC

As was pointed out elsewhere,[9,10] in the case of grain-oriented 50% iron and nickel magnetic core, the CMC agrees very well with the flux-control characteristics of the direct-voltage reset. In the latter, the group of minor hysteresis loops is observed experimentally to be almost rectangular as shown in Fig. 8. Here, the width of minor loop is seen to be a function of little more than the rate of flux change except in the portion near the negative saturation level. Therefore, it can be interpreted that the width of the dynamic hysteresis loop, due to the reset voltage of arbitrary waveform, is a function of the instantaneous rate of flux change. From this interpretation and the fact that the flux-control characteristics produced by direct-voltage reset coincides with the CMCs, these curves can be

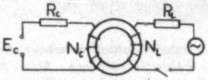

Fig. 10. Single-core circuit under d-c voltage reset

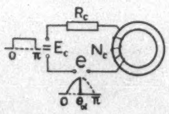

Fig. 11. Equivalent circuit of resetting half-cycle

interpreted as the relation between the instantaneous rate of flux change, $d\phi/dt$, and the control current, I_c. For the larger value of $d\phi/dt$, the straight portion of each curve should be extended linearly. This is due to the experimental fact that the increase of the width of minor loop in the case of direct-voltage reset is proportional to the increase of the rate of flux change for larger values of $d\phi/dt$ (see page 186 of reference 8).

In the case of direct-voltage reset

$$d\phi/dt=\Delta\phi/T/2=2f\Delta\phi \tag{3}$$

where $\Delta\phi$ is the amount of reset flux during the resetting half-cycle. If the ordinate of the control magnetization curve is taken as the average induced voltage, $2f\Delta\phi$, which is twice the value E_r/N_c given in equation 1, then the curve represents the relation between the rate of flux change, $d\phi/dt$, and the control current, I_c, for the reason discussed before. In the left half plane of Fig. 9, the CMC is shown, taking the control current as the abscissa and neglecting the residual voltage due to an imperfect magnetic saturation. Then the relation between $d\phi/dt$ and I_c is represented by the curve OMM'.

Flux Control by D-C Control Voltage Affected by CCR

In order to calculate the flux-control characteristics of the full-wave magnetic amplifier, it is convenient to know, as a preparation, the relation between the voltage impressed on the control winding and the rate of flux change affected by the finite CCR.

Consider the case of a single-reactor circuit shown in Fig. 10. At first, in the case of negligible CCR, the following relation is satisfied between the control voltage and the rate of flux change:

$$E_c=N_cd\phi/dt \tag{4}$$

This relation is represented by a straight line, OL_0 in Fig. 9, taking an appropriate unit of control voltage for the right half of the abscissa. If E_c is constant during the resetting half-cycle, then

$$E_c=2fN_c\Delta\phi \tag{4A}$$

where $\Delta\phi$ is the amount of reset flux during the half-cycle.

Next, taking into account the CCR, R_{cr}, the following relation is satisfied between the control voltage, E_{cr}, and the rate of flux change:

$$E_{cr}=N_cd\phi/dt+R_{cr}I_c \tag{5}$$

where the value of the control current is determined from the left half of Fig. 9 for a specified value of $d\phi/dt$. Then, taking an arbitrary point, K_0, on the ordinate, a straight line $T_0K_0P_r$ is drawn parallel to the abscissa. Let Q_0 be the point of intersection with the line OL_0, and T_0 the intersection with the CMC. Then, for the specified rate of flux change represented by the length of ordinate OK_0, the following relations are satisfied:

$$K_0Q_0=N_cd\phi/dt \tag{6}$$

$$T_0K_0=I_c \tag{7}$$

Using this value of I_c, the voltage on the CCR, R_{cr}, is calculated, which corresponds to the length Q_0P_r; that is

$$Q_0P_r=R_{cr}I_c \tag{8}$$

The point, P_r, is thus determined on the extension of the straight line, T_0Q_0.

If

$$K_0P_r=K_0Q_0+Q_0P_r \tag{9}$$

then, from equations 5, 6, 8, and 9,

$$E_{cr}=K_0P_r \tag{10}$$

Repeating the procedure, the curve OL_r is obtained which represents the relation between the rate of flux change and the voltage applied to the control winding, of which the resistance is R_{cr}.

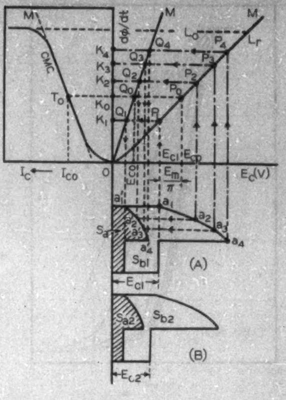

Fig. 12. Graphical analysis of flux-control characteristics

Graphical Analysis of Flux-Control Characteristics

Fig. 11 shows an equivalent circuit of a reactor core of the full-wave amplifier in its resetting half-cycle, where E_c is the d-c control voltage and e is the feedback voltage due to the induced emf of the other core in its gating period. The firing angle, $\theta\alpha$, of the reactor is given by the following relation:

$$\Delta\phi=(1-\cos\theta_\alpha)E_m/2\pi fN_c \tag{11}$$

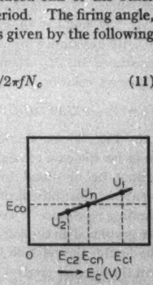

Fig. 13. Method of obtaining corrected control-voltage value

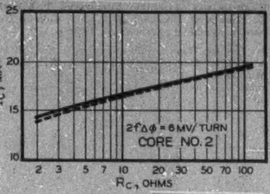

Fig. 14. Comparison of calculated data with the experiment

—— Measured
- - - Calculated

where E_m is the crest value of a-c supply voltage seen from the control winding, and $\Delta\phi$ is the resetting amount of flux of both cores in the case of the steady state.

An example of the graphical analysis to obtain the magnitude of control voltage for a specified amount of reset flux is shown in Fig. 12. In this particular example the steady-state firing angle, θ_α, is adjusted to $\pi/2$ radians. Then the amount of reset flux $\Delta\phi_r$, is given by the following equation:

$$\Delta\phi_r = (E_m/\pi)(1/2fN_c) \tag{12}$$

The problem is to find the correct value of control voltage which gives rise to the given amount of reset flux, $\Delta\phi_r$.

The average value of voltage absorbed in the reactor core during the resetting half-cycle is

$$\begin{aligned} E_{c2} &= 2fN_c\Delta\phi_r \\ &= E_m/\pi \end{aligned} \tag{13}$$

Next, by the method already explained in Fig. 9, the voltage E_{cp} which satisfies the following relation

$$E_{c0} + I_{c0}R_{cr} = E_{cp} \tag{14}$$

is calculated. The average value of volt-seconds which are fed back from the other core is

$$\bar{e} = 2fN_c\Delta\phi_r = E_m/\pi \tag{15}$$

Subtract $\bar{e}$ from E_{cp},

$$E_{cp} - \bar{e} = E_{c1} \tag{16}$$

Then the value of E_{c1} already obtained can be assumed to be the first approximate value of control voltage, which is being sought. Using E_{c1} and the feedback voltage e, the waveform of control-circuit voltage, $E_{c1}+e$, is drawn at A in Fig. 12.

At every instant in a resetting half-cycle, a portion of the voltage is consumed on the CCR and the remainder is absorbed in the reactor core. The graphical procedures to determine these two portions will be self-evident when compared with the case in Fig. 9. Thus, in the voltage waveform A of Fig. 12, the hatched area S_{a1}, which is the volt-seconds absorbed in the core, and the area S_{b1}, which is the volt-seconds on the CCR, can be determined. The half-cycle average of S_{a1} will be found to be a little larger than the voltage E_{c0} given by equation 13, due to the nonlinearity of the curve OL_r.

Next, choose a value of control voltage, E_{c2}, which is a little smaller than E_{c1} and draw the waveform B in Fig. 12, and repeat a similar procedure. The time average of the volt-seconds consumed in the core, S_{a2}, might be smaller than E_{c0}. The correct value of control voltage can be obtained by the interpolation method shown in Fig. 13. In this figure, the abscissa is the d-c control voltage and the ordinate is the time average of the volt-seconds consumed in the core. The point U_1 corresponds to E_{c1} and U_2 to E_{c2}. On the line U_1U_2, choose a point U_n which gives the value of ordinate equal to E_{c0}. Then its abscissa E_{cn} is the correct value of control voltage sought.

The control current is calculated easily by the equation

$$I_{cn} = E_{cn}/R_{cr} \tag{17}$$

Comparison of the Results of Analysis with Experimental Data

For various values of the CCR, the control current is calculated at the same constant flux-reset level which gives the firing angle, $\theta_a = \pi/1$. In Fig. 14 the values of control current, obtained both experimentally and by calculation, are plotted by taking the values of CCR on the abscissa. The good coincidence of the values shows the validity of the presented method.

The whole range of flux-control characteristics is calculated by procedures similar to that shown in Fig. 12, for two values of CCR, i.e., 10.44 ohms and 40.44 ohms. This is compared with the experimental results as shown in Fig. 15, which shows a good agreement of both data.

The data on magnetic cores used in the experiment are shown in Table I.

Table I. Data on Magnetic Cores

Core	Mean Diameter, Millimeters	Weight, Grams	Tape Thickness, Millimeters	Control Winding, Turns
Number 1	45	43.0	0.025	100
Number 2	30	35.7	0.05	50

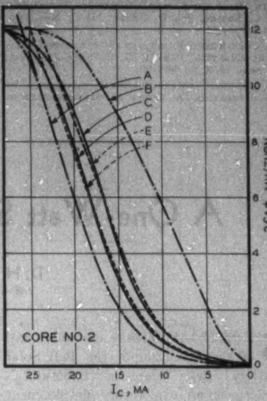

Fig. 15. Comparison of calculated flux-control characteristics with measured characteristics

A—CMC
B—$R_c \cong 0$
C—R_c = 10.44 ohms, measured
D—R_c = 40.44 ohms, measured
E—R_c = 10.44 ohms, calculated
F—R_c = 40.44 ohms, calculated

Conclusions

The effect of CCR on the flux-control characteristics of the full-wave magnetic amplifier is successfully elucidated under the ideal rectifier condition and for the magnetic cores with an almost rectangular hysteresis loop. The correlation between the control characteristics of the full-wave amplifier and its flux-control characteristics is comparatively simple. Therefore, the paper is a contribution to a deeper understanding of the mechanism of the full-wave magnetic amplifier.

Though this paper treats only the case of a steady-state condition, the transient phenomena can be discussed from the same viewpoint.

A One-Watt Solar Power Plant

D. H. SMITH
MEMBER AIEE

SHORTLY AFTER the announcement[1] of the invention of the Bell Solar Battery, Bell Telephone Laboratories undertook an exploratory development program with a twofold purpose. First, device designers wanted to learn how to make large quantities of silicon photodiodes, how to devise reliable connections to the active parts of the diode, and if possible, how to increase the realizable efficiency of conversion of sunlight to electricity. Second, system designers wished to find out how to use the new photodiodes in the most efficient and practical way in power plants for telephone equipment.

Reasonable progress has been made in this exploratory program. Efficient silicon photodiodes with reliable electrical contacts were fabricated in quantity for the exploratory program, and similar diodes are now available on the commercial market.

In addition, the fundamental system design problems have been explored and the solutions to a number of these problems have been obtained during the engineering planning for a recent field experiment.

This paper describes some of the preliminary work that culminated in the field experiment, including exploratory device development and engineering studies. Preliminary tests are discussed, and field test data are summarized.

Exploratory Development

An elementary solar battery, or silicon photodiode, is a small circular wafer cut from a single crystal of negatively-doped silicon. About one ten-thousandth of an inch below the surface of the wafer is a p-n junction, formed by the gaseous diffusion process at a carefully controlled temperature. A cross section of one of wafers is represented in Fig. 1. When a wafer 1 inch in diameter is exposed to sunlight, it intercepts about 1/2 watt of solar power. Theory predicts that about 1/5 of the solar power, or 100 milliwatts, can be made available to a resistance load connected across the diode. Practically however, only 25 to 50 milliwatts were obtainable from most of the diodes available for use in this exploratory development program, and the average power output per diode in the experimental plant was even lower due to paralleling losses.

When the active surface of the silicon photodiode is subjected to various intensities of illumination, the generated emf (electromotive force) varies somewhat. Therefore, if the load contains a source of energy, such as a battery, protection must be provided to prevent discharge of the battery through the photodiodes when the generated voltage falls below the emf of the battery.

DEVICE DEVELOPMENT

The diode fabrication program presented many challenging problems. Discussion of this part of the development can be found in the literature.[2–4] It is sufficient for this paper, however, to state that crystal purification, doping, diffusion, and contact techniques were worked out, which resulted in a relatively high yield of diodes that had very uniform characteristics. A typical diode was about 1 inch in diameter and four-hundredths of an inch thick. The diode potential in sunlight was about 1/2 volt on open circuit, and the short-circuit current was about 100 milliamperes. Because of internal resistance drop, the voltage under load was about 1/3 volt.

System studies, which paralleled the diode fabrication program, resulted in a recommendation for develpment of a power plant to produce 1 watt average and 10 watts peak. This power plant would be installed near Americus, Ga. at the site of the field tests of a new rural carrier telephone system.[5] It was planned that the solar power plant would furnish electricity to a transistorized carrier terminal for demonstration purposes. Since 432 diodes were required for the power plant, the diode development program was expanded to include the packaging of groups of 9 diodes in modular form. About 105 modules were fabricated; 48 for each of two complete power plants, plus 9 spare modules.

Let us examine a typical module, shown in Fig. 2. Nine photodiodes are mounted on a fiber board and are connected in series by means of etched or "printed" wiring. The board is suspended within a transparent Plexiglas case for mechanical protection. The case is filled with silicone oil to reduce loss of light due to refraction, and the case is sealed. When tested in full sunlight, a typical module delivered about 70 milliamperes at 2.5 volts.

The volt-amp (ampere) characteristics of module no. 8 were measured in the

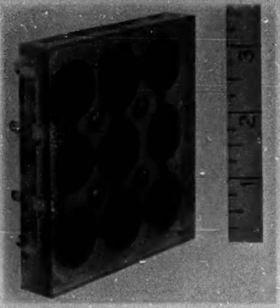

Fig. 2. Typical photo-module

laboratory in artifical (tungsten lamp) illumination, and are plotted in Fig. 3. The curve marked 1.45 for example, was obtained by exposing the module to a radiation intensity approximately equivalent to the average value of full sunlight in the continental United States, 1.45 gram-calories per square cm (centimeter) per minute, or 1,000 watts per square meter. The load on the module was varied from an open circuit (X-axis intercept at 4.7 volts) to a short circuit (Y-axis intercept of 71 milliamperes) and a continuous plot of the volt-amp relationship was obtained. Characteristics were taken at several different intensities; the minimum intensity was about 0.2 gram-calorie per square cm per minute, or about 140 watts per square meter, which is about the intensity of sunlight received on a very dull, cloudy day.

Laboratory tests were also made on individual diodes, and in Fig. 4 the power output and efficiency of a sample diode are plotted against light input. The radiant intensity was increased to a maximum of about 25 times normal sunlight. Output limiting, or saturation, is quite obvious, and there is not much doubt that internal loss is the dominant factor. Reduction of internal losses is an important goal particularly if light-concentrating techniques are to be employed in future exploratory studies.

Circuit Development

The power plant circuit is shown in Fig. 5. The charging source consisted of 48 9-cell photomodules, *M1-M48*, connected to provide a peak output of about 1/2 amp at 22 volts. A silicon diode gate, *CR1*, was used to prevent discharge of the storage battery through the low forward resistance of the photomodules.

Three discharge circuits were connected to the storage battery, *B*1. Fuse *F1* supplied the carrier transmission circuits with a nominal potential of 22 volts through a low-pass *L-C* filter. A bias potential of 16 volts was derived from the 22-volt source through a shunt voltage limiter consisting of a silicon varistor *CR2* operated in its breakdown region, and a ballast resistor *R1*. Fuse *F2* supplied 22 volts to carrier signaling apparatus.

Fuse *F3* supplied operating power to an audio oscillator which provided a 4,100-cycle tone through the low-voltage contact of a voltmeter relay to a remote detector. If the load voltage dropped below a safe value the low-voltage contact opened, causing an interruption in the tone and subsequent operation of the remote detector circuit.

System Development

The major system development problems: 1. to devise a weatherproof housing for 48 modules that could be aimed at a particular point in the sky and then locked in position, and 2. to provide means for storing energy for use during the night and during inclement weather. The final power plant design is shown in an over-all view in Fig. 6, a photograph taken at the test site near Americus, Ga.

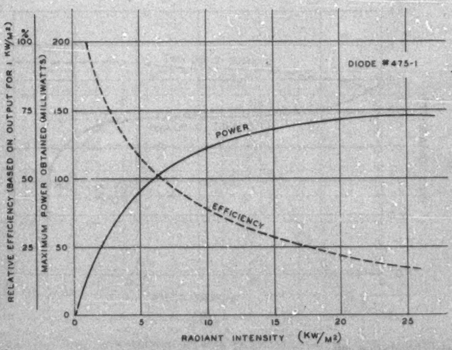

Fig. 4. Power output of a silicon photodiode

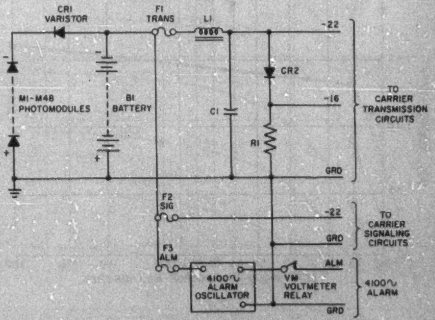

Fig. 5. Solar power plant circuit

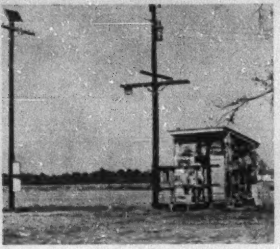

Fig. 6. View of solar battery field test site at Americus, Ga.

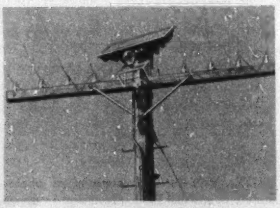

Fig. 7. Closeup of light transducer and reference standard at field test site

At the top of the left-hand telephone pole in Fig. 6 is the light transducer, a glass-front aluminum casting containing the 48 9-cell modules. Near the bottom of the pole are two white, die-cast aluminum boxes. The uppermost box contains the batteries used for energy storage, and a low-voltage alarm circuit. The box nearest the ground contains a type *P1* carrier system terminal. Adjacent is a test shack.

Fig. 7 is a closeup of the light transducer. Noticeable at the top are the stainless steel rods that served to discourage bird roosting and also acted as lightning rods. Just below the light transducer is a bracket upon which is mounted a secondary standard for measurement of radiant intensity. This is a specially selected silicon photodiode, mounted in a sealed glass bulb. The terminals of the secondary standard were connected to a continuous current recorder in the test shack.

Fig. 8(A) is a closeup of the storage battery box with the door open. At the top is a voltmeter relay and an audio oscillator which were part of the low-voltage alarm circuit. Along the hinged side is the filter used to isolate talking and signaling battery, and in the middle is the battery cover, shown open in Fig. 8(B). A total of 96 $1^1/_4$-volt storage cells were used to provide a 10-day reserve. These storage cells, furnished by a commercial vendor, were an experimental nickel-cadimum type which had several unusual features.

1. Each cell was hermetically sealed in a metal and plastic case which prevented the escape of moisture. Thus, the cells did not require the periodic addition of water, or any other routine maintenance. The importance of this feature would vary with the acessibility of the power plant to maintenance personnel.

2. To prevent the buildup of excessive pressure within the sealed container the cells used, in a novel manner, an electrochemical principle[6-8] which involves recombination of the gases formed within the cell during charge and continued overchange.

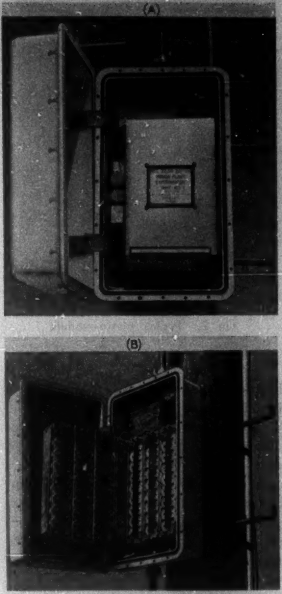

Fig. 8. Closeup of storage battery box

A—Internal cover closed
B—Internal cover open

3. The same mechanism which facilitated the internal recombination of evolved gases also reduced the magnitude of the voltage change associated with a given change in overcharge current, to a value significantly lower than for conventional unsealed storage batteries.

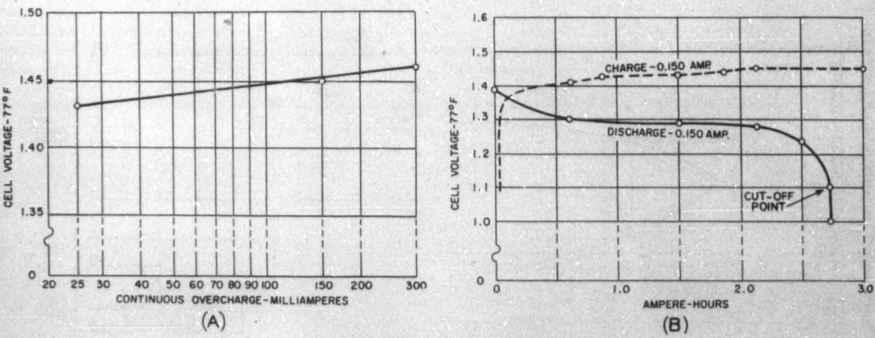

Fig. 9. Sealed nickel-cadmium cell

A—Overcharge characteristics

B—Charge-discharge characteristics

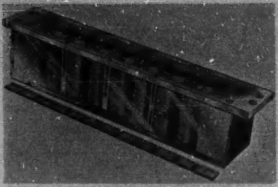

Fig. 10. A 16-cell module of storage battery

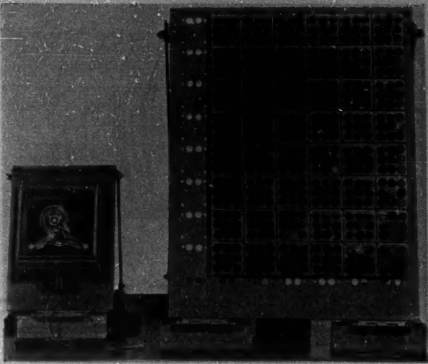
Fig. 12. Laboratory test assembly of silicon photomodules



This characteristic is illustrated in Fig. 9(A). The cells could be overcharged continuously at a rate as high as 0.3 amp. This capability of the sealed cells to operate with high charging rates and to take overcharge tended to minimize, through voltage limiting action, the changes in load voltage cause by diurnal changes in the sun's position with respect to the plane of the transducer and the annual changes in the inclination of the plane of the sun's orbit.

The sealed nickel-cadmium cell exhibited the flat charge and discharge characteristics of the nickel-cadmium system, illustrated in Fig. 9(B). Variations in battery voltage from day to night winter to summer, no load to full load, and maximum overcharge to end-of-discharge were so small that an auxiliary voltage regulator was not needed.

Sixteen cells were connected in series to form a 22-volt battery or "storage module," as shown in Fig. 10. Six of these storage modules, rated at about 2.5 amp-hours storage capacity each, were connected in parallel to form a storage battery rated at 22 volts and 15 amp-hours. Fifteen amp-hours was chosen after an investigation of the effect of observed solar radiation in Atlanta, Ga., and in particular, the frequency of extended periods of low radiation which might have resulted in a dangerously low state of charge of the storage battery. Fifteen amp-hours corresponded to a reserve of about 10 days.

On October 4, 1955, the carrier terminal was connected to the experimental power plant, and for the next 6 months all the power required by the terminal was supplied by the sun.

Preliminary Planning and Tests

Before the final design of the power plant could be formulated, it was necessary to determine how much electric energy could be obtained from the sun. Important factors in the planning were the amount of sunlight available at Americus, and the electrical and optical properties of the photodiodes. With these data available, the design effort could proceed.

Light Measurements at Americus

Measurements were made in 1954 of the amount of sunlight at the test site near Americus during the shortest day of the year, December 22. The maximum value on a cloudless day was found to be

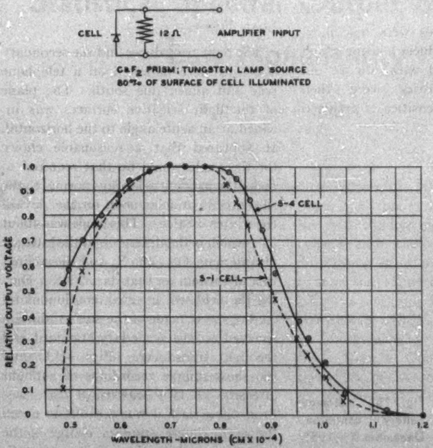


Fig. 11. Spectral response of secondary standard cells

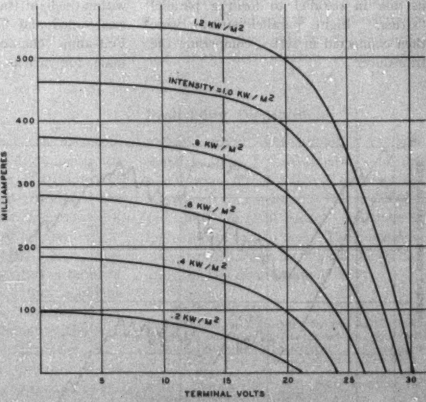

Fig. 13. Volt-amp characteristics of light transducer

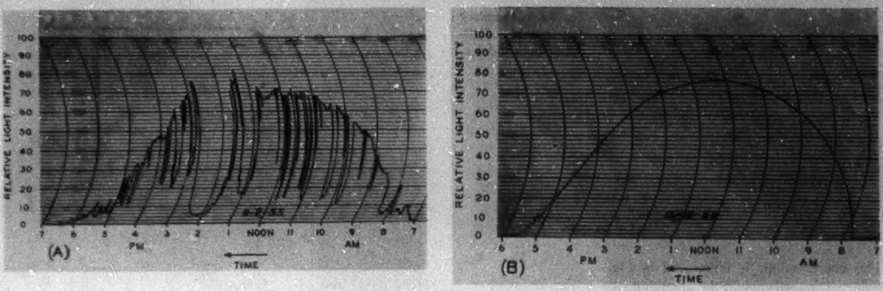

Fig. 14. Chart recordings of sunlight intensity

A—September 2, 1955: mostly sunny, scattered clouds

B—December 31, 1955: full sun, no clouds

0.91 gram-cal/cm²/min (calorie per cm² per minute), or about 633 watts per square meter, on a horizontal surface. Correction of this amount of radiant energy to a plane normal to the sun at its zenith gave 1.6 gram-cal/cm²/min, or about 1,100 watts per square meter which was used as the design value, or reference light.

EFFICIENCY OF SILICON MODULES

Each module received was subjected to a static volt-amp test in various intensities of artificial light. From these data were calculated the optimum load current and the conversion efficiency in reference light. Optimum load currrent varied from 61.5 milliamperes for module No. 10, to 116 milliamperes for module No. 60. The most inefficient module was No. 47 at 5.49% and the most efficient was No. 87 at 7.9%. The data were used to select six modules for connection in parallel to form a parallel "string." Eight parallel strings were then connected in series, comprising the transducer.

COLOR MATCHING

The spectral response of the photodiodes varied from cell to cell as shown in Fig. 11, and to a lesser extent from module to module. The effect of this variation on the plant design was minimized by selecting modules, to be connected in parallel, which had similar spectral response characteristics.

LOAD TESTS

After 48 suitable modules were selected for optimum load current and efficiency, they were assembled on a metal plate, as shown in Fig. 12, and were subjected to a load test, at a fixed voltage in clear sunlight. The results were in accordance with calculations, and it was decided to proceed with final assembly and shakedown tests.

SHAKEDOWN TESTS

The silicon modules were assembled within the light-transducer housing which was sealed and filled with silicone oil. Volt-amp characteristics were then taken for various intensities of artificial light, as shown in Fig. 13. Inspection of Fig. 13 reveals that at a peak radiant intensity of 1.2 kw per square meter, the power plant delivered 1/2 ampere at 20 volts, or 10 watts. This was very close to the design value. The storage batteries, alarm relay, and alarm oscillator were assembled in the storage housing, and the power plant was mounted on the roof of the Bell Telephone Laboratories building in New York, N. Y. The plant was operated into a resistance load for several weeks and performed satisfactorily. The total active silicon area was calculated to be 266.12 square inches and, in full sunlight, the over-all efficiency was found to be 5.8%. The plant was then crated and shipped to Americus, Ga.

Field Tests

LOAD TESTS

The light transducer and the secondary standard were mounted on a telephone pole and aimed due south. The plane of the light sensitive surfaces was inclined at an acute angle to the horizontal. It appeared that a reasonable choice for the angle would be that required to make the incident solar rays normal to the silicon cells at solar noon on the day of the winter solstice. This angle was about 55°, which is the difference of the latitude of Americus, Ga., 32° N, and the inclination of the sun on that day, 23°S. During the field test interval, continuous recordings were made of the sun's radiation received on the secondary standard and the light transducer. Figs 14(A) and (B) show sample recordings of sunlight intensity at two seasons of the year. From these data it was possible to check the approximate state of charge of the battery, including the minimum condition of charge during the period.

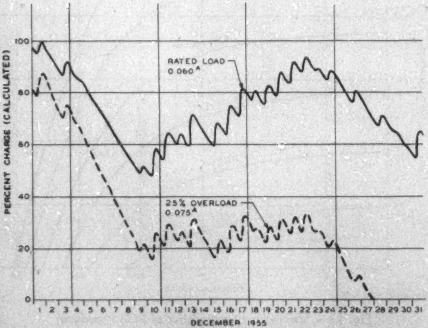

Fig. 15. Storage battery condition, December 1, 1955 through December 31, 1955

The approximate state of charge of the storage battery was calculated, by a simple numerical procedure, on a day-to-day basis during the test. A portion of these calculated data are plotted in Fig. 15, covering the interval during which the lowest state of charge was expected. The computation was based on an assumed value of average load current, and on assumed relationships between charging efficiency and state of charge of the storage battery. On the basis of the calculations, it was concluded that that the battery was half charged on December 10, 1955. It was computed that a load current 25% higher, 75 milliamperes, would have discharged the storage battery completely by December 27, 1955.

Although dirt was deposited on the glass face of the light transducer, natural washing during rainy periods was very effective, and the residual light attenuation, as measured at the Laboratories upon completion of the field tests, was less than 10%. This may not be typical of any other location. No bird deposits were found on the transducer, and no lightning strikes were reported.

The power plant was judged relatively easy to install. Aiming of the transducer for optimum altitude was simplified by a built-in quadrant and plumb-line arrangement. The azimuth setting was made with the help of a compass. A critical inspection of the plant after its return revealed no mechanical damage to either the light transducer or the storage assembly. Although the transducer weighed 125 pounds, including 2 gallons (16 pounds) of silicone oil, and had been exposed to a wide range in ambient temperature, no leaks developed in the gaskets nor was there any evidence of undue mechanical strain.

On the basis of the tests performed in the laboratory and in the field, it was concluded that technical feasibility had been demonstrated for a power plant capable of furnishing about 1 watt.

Economic Considerations

An analysis of the cost of the experimental power plant revealed that it could not compete on an annual charge basis with either of two standard power plants for the type *P1* carrier system. The two standard plants, described in detail elsewhere,[9] consist of a regulated rectifier and an auxiliary storage battery for reserve or, where commercial alternating current is not economically available, a nonrechargeable primary battery of the air-depolarized type.

The principal sources of expense in the solar power plant were the photodiodes and the storage battery. Photodiodes having higher efficiency than those used during the test are now commercially available at about $2.00 per cell, which represents a 10-to-1 price reduction in less than 2 years. Another major price reduction, together with a reduction in the cost of storage elements, could make a solar power plant of the type described competitive with the air-depolarized battery at least for continuous power consumption levels in the order of 1 watt.

Statistical Spectral Output of Power Law Nonlinearity

OTTO J. M. SMITH
MEMBER AIEE

One of the objectives of analyzing a system is to determine if there are periodic oscillations and, if so, what their amplitude and frequency will be; another objective is to determine the magnitudes of output errors and output powers, when the statistical character of the input signal and noises are known. Methods are given for calculating the output power and the error power for nonlinearities describable by power series for Gaussian and for certain other special kinds of input signals.

The objectives of this statistical treatment of nonlinearities are 1. to present a method of describing non-Gaussian random signals, 2. to show the harmonic power spectrum generated by nonlinearities from random signals, 3. to show the calculation of the output power and the error power in a nonlinear system, and 4. to show the calculation of criteria for stability in nonlinear systems. Non-Gaussian signals will be described in terms of the mechanism by which they could be made from a Gaussian source: either power law devices, or discontinuities such as hysteresis, dead zone, saturation, etc.

The harmonic power spectrum at the output of a nonlinearity is related to the squares, cubes, and higher powers of the autocorrelation function. The output has both harmonic power uncorrelated with the input, and fundamental components which are correlated with the input. The cross correlation (CC) between input and output of a nonlinearity is a transference which can be used both for stability tests and for the determination of the useful output.

Probability Distribution

One method of describing a random signal is to plot the probability of the signal, when it is less than a certain voltage, versus that voltage. This is called a probability integral curve. Its range is limited from zero to one. The normal or Gaussian distribution with zero mean has a probability distribution of

---

Paper 59-265, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted December 30, 1957; made available for printing December 17, 1958.

Otto J. M. Smith is with the University of California, Berkeley, Calif.

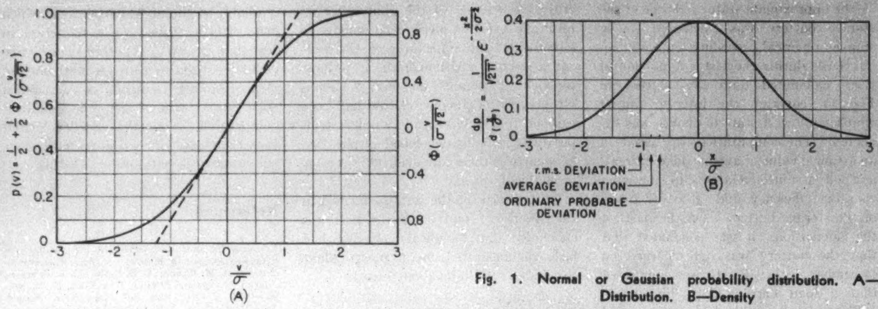

Fig. 1. Normal or Gaussian probability distribution. A—Distribution. B—Density

$$p(v)=\frac{1}{2\pi}\int_{\infty}^{x=v}\epsilon^{-\frac{x^2}{2\sigma^2}}d\frac{x}{\sigma}=\frac{1}{2}+\frac{1}{\sigma\sqrt{2\pi}}\int_0^{x=v}\epsilon^{-\frac{x^2}{2\sigma^2}}dx \qquad (1)$$

The plot of this curve in Fig. 1(A) is called an ogive. If v is plotted versus probability p on probability integral coordinates (Keuffel & Esser type no. 358-23), it is a straight line.

The derivative of the curve of Fig. 1 is the probability density, or differential probability. It is the familiar bell-shaped curve with a mean of zero volts, and inflection points at $\pm\sigma$ volts; see Fig. 1(B).

$$p'=\frac{dp}{dx}=\frac{1}{\sigma\sqrt{2\pi}}\epsilon^{-\frac{x^2}{2\sigma^2}} \qquad (2)$$

This is the probability of a random Gaussian voltage between the values x and $x+dx$. Considering the area under this curve, the ordinary probable deviation is the line which divides each half of the area into halves. This is $\pm 0.674\ \sigma$ voltage deviations which are exceeded half of the time. The center of gravity of each half, or the average deviation, is $0.798\ \sigma$ volts. This value would be delivered by a full-wave linear averaging rectifier. It is the integral of equation 2 times x, over one half of the curve only. The integral over all x is called the first moment, and is zero because the $-x$ terms contribute as much negative weight as do the $+x$ terms positive weight.

The radius of gyration of the area about the mean (zero volts) is the rms voltage σ; this is the second moment. It is the value of the random signal which a dynamometer meter would read. The d-c voltage which a full-wave square-law averaging rectifier would deliver is σ^2.

The mth even moment is

$$M_m=\int_{-\infty}^{+\infty}\frac{x_m}{\sqrt{2\pi}}\epsilon^{-\frac{x^2}{2x^2}}d\left(\frac{x}{\sigma}\right)=1\times3\times5\ldots(m-1)\sigma^m\ (m\text{ even}) \qquad (3)$$

The third moment and all odd moments of a Gaussian signal are zero. If this signal is passed through some full-wave device which reverses the sign of the negative voltages, the computed moments are called the absolute moments.

For this general case, when only half the distribution is used, or when the odd powers of x are all given positive signs, the absolute moments either even or odd, are

$$M_m=2\int_0^{\infty}\frac{x^m}{\sqrt{2\pi}}\epsilon^{-\frac{x^2}{2\sigma^2}}d\left(\frac{x}{\sigma}\right)=\frac{2^{m/2}\sigma^m}{\sqrt{\pi}}\Gamma\left(\frac{m+1}{2}\right) \qquad (4A)$$

When m is odd

$$M_m=\left(\frac{m-1}{2}\right)!\,\frac{2^{m/2}\sigma^m}{\sqrt{\pi}} \qquad (4B)$$

The coefficient in the moment equation will appear many times in subsequent work, and an abbreviation for it is desirable. The coefficient will be defined in terms of a number n, which is one less than the order of the moment; n equals $(m-1)$. The coefficient for the even moments is

$$c_n=c_{m-1}=1\times3\times5\times7\ldots n=\frac{n!}{\left(\frac{n-1}{2}\right)!(n-1)/2} \qquad (5A)$$

When a Γ function is substituted, this series becomes exactly the same as the coefficient in the absolute moment.

$$c_n=c_{m-1}=\frac{2^{(n+1)/2}\Gamma\left(\frac{n}{2}+1\right)}{\sqrt{\pi}}=\frac{2^{m/2}\Gamma\left(\frac{m+1}{2}\right)}{\sqrt{\pi}} \qquad (5B)$$

The gamma function is defined by

$$\Gamma(q)=(q-1)!=\int_0^{r=\infty}r^{q-1}\epsilon^{-r}dr \qquad (5C)$$

This coefficient is valid for all values of n greater than minus 2, and all values of m greater than minus 1; it is not restricted to integer values. With this notation, the absolute moment of any integer or fractional order m of a Gaussian distribution is

$$M_m=c_{m-1}\sigma^m=c_n\sigma^{n+1}=M_{n+1} \qquad (6)$$

High-Order Cross Correlations

The higher moments of the probability distribution of a signal have a meaning which is related to the results obtained from laboratory tests; they are components of the correlation between one power of the signal and a different power. The latter can be measured in practice more easily than the moments, and the transferences of nonlinearities will be in terms of these cross-correlations (CC's), and not the higher moments. The transference will be derived for the general case of two partially correlated signals, from which the special case of a single signal follows directly.

Fig. 2 shows two partially correlated signals. The CC between them is the time average of their product as a function of the time shift (advance) for the second wave.

$$\psi_{ab}(\tau)=\lim_{T\to\infty}\frac{1}{2T}\int_{t=-T}^{t=+T}a(t)b(t+\tau)dt=\mathrm{CC}(a,b) \qquad (7)$$

The CC between the mth power of the voltage a, and the nth power of the voltage b is

$$\psi_{a^mb^n}(\tau)=\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{+T}a^m(t)b^n(t+\tau)dt=\mathrm{CC}(a^m,b^n) \qquad (8)$$

The rms value of the signal a will be denoted by σ_a, and for signal b by σ_b; $\psi(0)$ is the cross power in units of volts to the $(m+n)$th power.

The normalized autocorrelation for voltage a is defined by

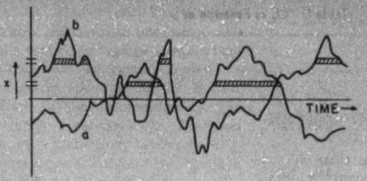

Fig. 2. Time curves of two random functions, illustrating determination of CC as integration over all amplitudes of product of amplitudes, times joint second-order probability density

$$\rho_{aa}(\tau)=\frac{\psi_{aa}(\tau)}{\sigma_a{}^2} \tag{9A}$$

This has a value of unity when τ is zero. The normalized CC is defined by

$$\rho_{ab}(\tau)=\frac{\psi_{ab}(\tau)}{\sigma_a\sigma_b} \tag{9B}$$

This has a value which is always less than one. It equals one, at zero τ, for perfectly correlated signals.

Second-Order Probability Density

The higher-order CC can be derived from probability distributions, instead of from time integrals. The time integral method takes the time average of the value of a times the value of b shifted by a fixed time τ. The density method performs the integration vertically in Fig. 2 instead of horizontally. It takes the product of voltage a times voltage b times the probability that a and b have these particular values simultaneously, and integrates over all values. The simultaneous restriction includes the time shift on b, and therefore includes the τ variable of the CC. More specifically, in Fig. 2 the CC is the integral over all w and x of wx, times the joint probability of a being between w and $w+dw$, while simultaneously b is between x and $x+dx$.

The joint (second-order) probability density for two Gaussian signals is

$$(\partial p_{ab},\partial p_{ab})=\frac{1}{2\pi\sigma_a\sigma_b\sqrt{1-\rho_{ab}{}^2}}\exp-\frac{1}{2(1-\rho_{ab}{}^2)}\left[\left(\frac{w}{\sigma_a}\right)^2-2\times\rho_{ab}\left(\frac{w}{\sigma_a}\right)\left(\frac{x}{\sigma_b}\right)+\left(\frac{x}{\sigma_b}\right)^2\right]\partial w\partial x \tag{10}$$

That this is correct will be shown by the fact that it integrates to the CC; $\rho_{ab}(\tau)$ is the normalized CC

$$\psi_{ab}=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}wx\left(\frac{\partial p_{ab}}{\partial w},\frac{\partial p_{ab}}{\partial x}\right)dw\,dx \tag{11}$$

For convenience in integrating, change the variables to y equals w/σ_a, and z equals x/σ_b. Complete the square in the exponent, so that the term enclosed by brackets in equation 10 becomes

$$y^2-2\rho_{ab}\,yz+(\rho_{ab}\,z)^2+z^2(1-\rho_{ab}{}^2) \tag{12}$$

Change variables a second time, letting u^2 equal the squared term divided by the constants in the exponent

$$u=\frac{(y-\rho_{ab}z)}{\sqrt{2}\sqrt{1-\rho_{ab}}} \tag{13}$$

For simplicity, the subscript to ρ can be omitted, and the complete integral in equation 11 then becomes

$$\psi ab=\frac{\sigma_a\sigma_b\sqrt{1-\rho^2}}{\pi}\int_{-\infty}^{+\infty}z\epsilon^{-\frac{z^2}{2}}\times dz\int_{-\infty}^{+\infty}\left(u+\frac{\rho z}{\sqrt{2}\sqrt{1-\rho^2}}\right)\epsilon^{-u^2}du \tag{14}$$

Because of symmetry

$$\int_{-h}^{h}u\epsilon^{-u^2}du=0 \tag{15}$$

The last term in equation 14 is the error integral, or probability integral, defined as

$$\Phi(x)=\frac{2}{\sqrt{\pi}}\int_0^x\epsilon^{-u^2}du \tag{16}$$

Since $\Phi(-x)$ equals $-\Phi(x)$, and $\Phi(\infty)$ is one, the CC becomes

$$\psi_{ab}=\frac{\sigma_a\sigma_b\rho}{\sqrt{2\pi}}\int_{-\infty}^{+\infty}z^2\epsilon^{-\frac{z^2}{2}}dz=\sigma_a\sigma_b\rho_{ab} \tag{17}$$

This reduces to an identity, which demonstrates the method.

Odd-Order CC

The CC between signal a and the nth power of signal b is the integral of the product of w times x^n times the same joint probability that these signals have the values w and x simultaneously.

$$\psi_{ab}n=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}wx^n\left(\frac{\partial p_{ab}}{\partial w},\frac{\partial p_{ab}}{\partial x}\right)dw\,dx \tag{18}$$

$$\psi_{ab}n=\frac{\sigma_a\sigma_b{}^n\sqrt{1-\rho^2}}{\pi}\int_{-\infty}^{+\infty}z^n\epsilon^{-\frac{z^2}{2}}dz\times\int_{-\infty}^{+\infty}\left(u+\frac{\rho z}{\sqrt{2}\sqrt{1-\rho^2}}\right)\epsilon^{-u^2}du \tag{19A}$$

Evaluating the last integral as before yields

$$\psi_{ab}n=\frac{\sigma_a\sigma_b{}^n\rho}{\sqrt{2\pi}}\int_{-\infty}^{+\infty}z^{n+1}\epsilon^{-\frac{z^2}{2}}dz \tag{19B}$$

A considerable similarity between this equation and equation 3 for the higher moments of b is apparent. The integral is zero when n is even. There is correlation only for the odd powers. Evaluating the integral above, yields the odd-order CC

$$\psi_{ab}n=\sigma_a\sigma_b{}^n\rho_{ab}\times1\times3\times5\ldots n=c_n\sigma_a\sigma_b{}^n\rho_{ab} \tag{20A}$$

This is valid only for n odd.

The coefficient is the same as in the $(n+1)$th order moment of signal b. The CC may therefore be written

$$ab^n=\left(\frac{M_{n+1}}{\sigma_b{}^2}\right)\rho_{ab}(\tau)\sigma_a\sigma_b \tag{20B}$$

The coefficient for the nth power CC is the ratio of the next higher moment to the mean square. A higher-order normalized correlation can be defined as

$$\rho_{ab}{}^n=\frac{\psi_{ab}n}{\sigma_a\sigma_b{}^n\times1\times3\times5\ldots n} \tag{21}$$

In this particular case, this reduces to ρ_{ab} when equation 20 is substituted.

Fractional-Order CC

When n is even, b^n is always positive, and there is no correlation between a and b^n. But circuits can be built to deliver $b|b^{n-1}|$ which has the sign of b. These can include fractional exponents and reciprocals of fractional exponents. For this general case, in which b^n has the sign of b, there is an absolute CC, given by changing the integral in equation 19(B) to two times the integral from zero to infinity.

$$\psi_{ab}n=\frac{\sigma_a\sigma_b{}^n}{\sqrt{2\pi}}\left[2^{\frac{n}{2}+1}\Gamma\left(\frac{n}{2}+1\right)\right]=c_n\sigma_a\sigma_b{}^n\rho_{ab} \tag{22}$$

This holds for any n greater than minus 2. When n is minus one, the coefficient c is unity.

Higher-Order CCs

The CC between the mth power of a and the nth power of b is obtained by substituting w^m and x^n in equation 11. Completing the square in the exponent as before yields

$$\psi_{a^mb^n}=\frac{\sigma_a{}^m\sigma_b{}^n(\sqrt{2}\sqrt{1-\rho^2})^m}{\pi\sqrt{2}}\times\int_{-\infty}^{+\infty}z^n\epsilon^{-\frac{z^2}{2}}dz\int_{-\infty}^{+\infty}\times\left[u+\frac{\rho z}{\sqrt{2}\sqrt{1-\rho^2}}\right]^m\epsilon^{-u^2}du \tag{23}$$

The last integral may be rewritten as

$$\int_{-\infty}^{+\infty} f(u)\epsilon^{-u^2}\,du=\int_0^{\infty} f(u)\epsilon^{-u^2}\,du-$$

$$\int_0^{\infty} f(-u)\epsilon^{-(u^2)}\,d(-u)$$

$$=\int_0^{\infty} (f(u)+f(-u))\epsilon^{-u^2}\,du \qquad (24)$$

where $f(u)$ is the binominal series expansion of the bracket to the mth power

$$\left[u+\frac{\rho z}{\sqrt{2}\sqrt{1-\rho^2}}\right]^m$$

in equation 23.

Performing this expansion, adding the two series, and integrating each term, yields

$$\int_{-\infty}^{+\infty} (u+\alpha z)^m \epsilon^{-u_2}\,du$$

$$=2\sqrt{\pi}\left\{\frac{(\alpha z)^m}{2}+\frac{m(m-1)}{2}\,\frac{(\alpha z)^{m-2}}{2^2}+\right.$$

$$\frac{m(m-1)(m-2)(m-3)c_3}{4!}\,\frac{(\alpha z)^{m-4}}{2^3}+$$

$$\ldots+\frac{m!c_{2q-3}}{(m-2q+2)!(2q-2)!}\times$$

$$\frac{(\alpha z)^{m-2q+2}}{2^q}+\ldots+$$

$$\left.\begin{bmatrix} 2^{-\frac{m}{2}-1}\,c_{m-1}, \text{ if } m \text{ is even} \\ \text{or} \\ \alpha z^{2}{}^{-\frac{m+1}{2}}\,c_{m-2}, \text{ if } m \text{ is odd}\end{bmatrix}\right\} \qquad (25)$$

where α is $\rho/\sqrt{2}\sqrt{1-\rho^2}$. Substituting this series back into equation 23, and integrating each term separately, yields $\psi_{a^mb^n}=$ zero, if $m+n$ is odd. (This is for even powers of the signal all positive.) For m and n both even or both odd

$$\psi_{a^mb^n}=\sigma_a{}^m\sigma_b{}^n\Bigg[c_{m+n-1}\rho^m+$$

$$\frac{m(m-1)}{2!}\,c_{m+n-3}(1-\rho^2)\rho^{m-2}+$$

$$\frac{m(m-1)(m-2)(m-3)}{4!}\times$$

$$c_3c_{m+n-5}(1-\rho^2)^2\,\rho_{m-4}+\ldots+$$

$$\frac{m!}{(m-2q+2)!(2q-2)!}c_{2q-3}\times$$

$$c_{m+n-2q+1}(1-\rho^2)^{q-1}\rho^{m-2q+2}+\ldots+$$

$$\begin{cases} c_{m-1}\,c_{n-1}(1-\rho^2)^{\frac{m}{2}} \text{ if } m \text{ is even} \\ \text{or} \\ c_{m-2}\,c_n\rho(1-\rho^2)^{\frac{m-1}{2}} \text{ if } m \text{ is odd}\end{cases} \qquad (26)$$

Table I. CC as Function of ρ

m	n	$\sigma_a{}^{-m}\sigma_b{}^{-n}\psi_{a^mb^n}$
1	1	ρ*

m, even	n, even	$c_{m-1}c_{n-1}\left(1+\frac{mn}{2}\rho^2+\frac{m(m-2)n(n-2)}{4!}\rho^4+\frac{m(n-2)(m-4)n(n-2)(n-4)}{6!}\rho^6+\ldots+\right)$ $\frac{\left(\frac{m}{2}\right)!\left(\frac{n}{2}\right)!2^{2k}}{\left(\frac{m}{2}-k\right)!\left(\frac{n}{2}-k\right)!}\rho^{2k}$

* This term means $\rho_{ab}(\tau)=[\psi_{ab}(\tau)]/[\sigma_a\sigma_b]$.

There are k terms, where k equals m or n, whichever is smaller.

The CC from input to output of a single nonlinearity is also given by the column for n equals unity in Tables I and II. The input voltage is $\sigma_a=\sigma_b$, and $\rho_{ab}(\tau)$ is the input autocorrelation; m is the order of the power law nonlinearity. The autocorrelation of the output of this single nonlinearity is given by the row for $m=n=$ order of nonlinearity.

Either the specific tables, I and II, or a careful examination of the general series in the foregoing will reveal that

$$\frac{\psi_{a^mb^n}}{\sigma_a{}^m\sigma_b{}^n}=\frac{\psi_{a^nb^m}}{\sigma_a{}^n\sigma_b{}^m} \qquad (27)$$

The tables give the CC as a function of τ between the outputs of two nonlinear components. The a component is a power law of the mth order and the b component is a power law of the nth order. The inputs to each have gaussian probability distributions and are σ_a and σ_b volts rms respectively. The normalized CC between the inputs is $\rho_{ab}(\tau)$.

The power spectrum is the Fourier transform of the autocorrelation. The power in volts squared is $\psi(0)$. The power output of a nonlinearity is also given by these cross-power tables. For the self-power, set $a=b$, $m=n$, and $\rho=$unity. The increase in power is apparent. Furthermore, much of it is contributed by the higher powers of ρ, which have small time constants, and represent the higher harmonics generated by the nonlinearity. These higher harmonics are not correlated (in the usual sense) with the input, as the $n=1$ column shows. In fact, the only correlation with the input is a term proportional to the input autocorrelation.

Nonlinear Network

Fig. 3 shows the mechanism of action of a general nonlinearity expressed as a power series. The input θ_i is Gaussian with a power of σ^2 and a normalized autocorrelation of ρ.

The output θ_o is

$$\theta_o=n_1\theta_i+n_2\theta_i^2+n_3\theta_i^3+n_4\theta_i^4+\ldots \tag{28}$$

The cubic term delivers a component θ_3 to the output, where θ_3 is equal to $n_3\theta_i^3$. This component has an autocorrelation of

$$\psi_{33}=n_3^2\psi_{i^3i^3}=n_3^2(3\rho+2\rho^3)\sigma^6 \tag{29}$$

In a similar manner, the autocorrelation of each component in the output may be written from the previous table and multiplied by the gain coefficient squared.

All of the odd outputs are cross-correlated with each other. For example.

$$\psi_{35}=n_3n_5\psi_{i^3i^5}=n_3n_5\ 15(3\rho+4\rho^3)\sigma^8 \tag{30}$$

The even outputs are also cross-correlated with each other, but there is no correlation between the sums of the odds and the sums of the evens.

The CC between the input and the output of the entire system is due only to the odd terms. It is the sum of all of the $n-1$ terms in the table. Factoring out $\sigma\rho$ yields

$$\psi_{io}(\tau)=\sigma\rho(n_1\sigma+n_3c_3\sigma^3+n_5c_5\sigma^5+n_7c_7\sigma^7+\ldots)=N_1\sigma\rho(\tau)=\left(\frac{N_1}{\sigma}\right)\psi_{ii}(\tau) \tag{31A}$$

Equation 31(A) can serve as the definition of the equivalent gain N_1/σ.

This series may be written in terms of the moments of the distribution:

$$\psi_{io}=\rho\sigma^2\left[n_1+n_3\left(\frac{M_4}{\sigma^2}\right)+n_5\left(\frac{M_6}{\sigma^2}\right)+n_7\left(\frac{M_8}{\sigma^2}\right)+\ldots\right] \tag{31B}$$

Nonlinear Gain

The fundamental gain of a device is the ratio of the sinusoidal output divided by the sinusoidal input for a single frequency. When the signal is random, the fundamental gain is the cross-power spectral operator, which is the ratio of the cross power to the input power. For dynamic devices, the gain is a function of frequency. For nondynamic nonlinearities the gain is a function of the voltage amplitude.

The gain varies with the signal level and the coefficients of the higher powers. Let N_1 stand for the bracket in equation 31(A) which is a function of the n coefficients and σ. The Fourier transform of the cross-power spectral density of the nonlinearity is

$$\mathfrak{F}\psi_{io}(\tau)=\phi_{io}(\lambda)=\left(\frac{N_i}{\sigma}\right)\phi_{ii}(\lambda) \tag{32}$$

This includes all of the power terms in the output that are correlated with the input, and that have a bearing on the stability of a system when reintroduced into the input through linear feedback channels. The equivalent transference of a single nonlinearity in a linear system, with a Gaussian input, is N_1/σ. This is a variable, amplitude-dependent gain, without phase shift, and independent of frequency for a power series nonlinearity. The signs of the n coefficients determine whether the gain increases or decreases with amplitude. For stability studies this transference can be plotted as a scale along the 180-degree line in the L plane, (log gain versus phase), and marked with the rms level at the input to the nonlinearity.

The total output power of a nonlinearity can be derived from the autocorrelation or the self-power spectrum. There are CC between all of the even-power components and between all of the odd-power components. The autocorrelation of the output in Fig. 3 is the sum of all terms in the previous tables, each multiplied by the appropriate network coefficient. Notice that every CC term appears twice. Write all of these, and factor out the various powers of ρ. The coefficient of each power of ρ can be arranged in the order of increasing subscripts, and by induction it can be shown that every doubly infinite series is a square. The output autocorrelation is

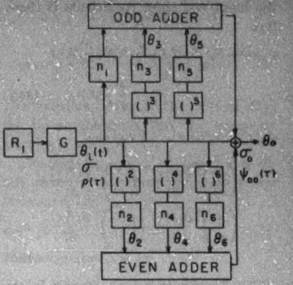

Fig. 3. General nonlinearity consisting of sum of all powers of input time function. There is no correlation between the output of odd adder and output of even adder

$$\begin{aligned}\psi_{oo}(\tau)={}&\rho(n_1\sigma+n_3c_3\sigma^3+n_5c_5\sigma^5+\ldots)^2+\\&\frac{\rho^3}{3!}(2n_3c_3\sigma^3+4n_5c_5\sigma^5+6n_7c_7\sigma^7+\ldots)^2+\\&\frac{\rho^5}{5!}(2\times4n_5c_5\sigma^5+4\times6n_7c_7\sigma^7+\ldots)^2+\\&\ldots+(n_2\sigma^2+n_4c_3\sigma^4+n_6c_5\sigma^6+\ldots)^2+\\&\frac{\rho^2}{2!}(2n_2\sigma^2+4n_4c_3\sigma^4+6n_6c_5\sigma^6+\ldots)^2+\\&\frac{\rho^4}{4!}(2\times4n_4c_3\sigma^4+4\times6n_6c_5\sigma^6+\\&6\times8n_8c_7\sigma^8+\ldots)^2+\ldots\end{aligned} \tag{33}$$

The coefficients of the even powers of ρ for zero average input will be defined as

$$N_k=\left[\frac{k}{2}!2^{\frac{k}{2}}n_kc_{k-1}\sigma^k+\frac{\left(\frac{k}{2}+1\right)!2^{\frac{k}{2}+1}}{1!2}n_{k+2}c_{k+1}\sigma^{k+2}+\frac{\left(\frac{k}{2}+2\right)!2^{\frac{k}{2}+2}}{2!2^2}\times n_{k+4}c_{k+3}\sigma^{k+4}+\ldots\right] \tag{34}$$

The coefficients of the odd powers of ρ for zero average input will be defined as

$$N_r=\left[\left(\frac{r-1}{2}\right)!2^{\frac{r-1}{2}}n_rc\sigma_r{}^r+\frac{\left(\frac{r+1}{2}\right)!2^{\frac{r+1}{2}}}{1!2^2}n_{r+2}c_{r+2}\sigma^{r+2}+\frac{\left(\frac{r+3}{2}\right)!2^{\frac{r+3}{2}}}{2!2^2}n_{r+4}c_{r+4}\sigma^{r+4}+\ldots\right] \tag{35}$$

The output autocorrelation in terms of

the input and these coefficients is therefore

$$\psi_{oo}(\tau)=N_0^2+\rho N_1^2+\frac{\rho^2}{2!}N_2^2+\frac{\rho^3}{3!}N_3^2+\frac{\rho^4}{4!}N_4^2+\ldots \quad (36A)$$

$$\psi_{oo}(\tau)=+N_0^2+\left(\frac{N_1}{\sigma}\right)^2\psi_{ii}(\tau)+\left(\frac{N_2}{\sigma^2}\right)^2\frac{\psi_{ii}^2(\tau)}{2!}+\left(\frac{N_3}{\sigma^3}\right)^2\frac{\psi_{ii}^3(\tau)}{3!}+\left(\frac{N_4}{\sigma_4}\right)^2\frac{\psi_{ii}^4(\tau)}{4!}+\left(\frac{N_5}{\sigma^5}\right)^2\frac{\psi_{ii}^5(\tau)}{5!}+\ldots \quad (36B)$$

The Fourier transform of this is the power spectrum. The output power in volts squared is expressed in equation 36(A) when τ is zero and ρ is unity:

$$\psi_{oo}(0)=N_0^2+N_1^2+\frac{N_2^2}{2!}+\frac{N_3^2}{3!}+\frac{N_4^2}{4!}+\ldots \quad (37)$$

This may contain considerable harmonic power, since N_1^2 is the only term resulting from the useful output power, which correlates with the input.

The N^2 coefficients are powers in volts squared of combinations of harmonics. The significance of the N coefficients may be shown by considering, for example, N_3^2. This determines the magnitude of ψ_{ii}^3 in the output. To find these specific terms, expand the cube of the autocorrelation.

$$\psi_{ii}^3=\left(a\epsilon^{-\frac{|\tau|}{T_1}}+b\epsilon^{\frac{|\tau|}{T_2}}+c\epsilon^{-\frac{|\tau|}{T_3}}+\ldots\right)^3$$
$$=a^3\epsilon^{-\frac{3|\tau|}{T_1}}+b^3\epsilon^{-\frac{3|\tau|}{T_2}}+3a^2b\epsilon^{-|\tau|\left(\frac{2}{T_1}+\frac{1}{T_2}\right)}+3ab^2\epsilon^{-|\tau|\left(\frac{1}{T_1}+\frac{2}{T_2}\right)}+\ldots \quad (38)$$

N_3 therefore controls the magnitude of the third harmonics and the third-order beat frequencies, i.e., one frequency plus twice another frequency.

In the power density spectrum, N_3 controls the magnitude or residues of an additional set of poles which are added to the original ones. Additional poles are found at three times the radial distance from the origin to each of the original poles. Additional poles are at all possible combinations of the sum of one original position plus twice the radial distance from the origin to each of the other poles. In a similar manner, N_5 controls the magnitude of an additional set of fifth-order beat frequency poles in the output spectrum.

Equation 36 can be used to calculate the output power of a nonlinear element. The first term is the direct current from rectification. The second term is all of the output power which correlates with the input, and the other terms are the harmonic powers. In a feedback system, if the nonlinearity is near the system output, these harmonic terms contribute to the error. Since they are introduced within the loop, at a high power-level point, they will be degenerated by the loop gain. They may be considered as noise inputs, whose amplitudes correlate with the signal amplitude at the input to the nonlinearity. The harmonic power does not have a Gaussian distribution. It has components which are the cubes and higher powers of a Gaussian distribution. If these terms are more objectionable than an equal amount of power in an error with Gaussian distribution, then the minimum error power is not the best criterion of design to use.

Feedback Loop with Nonlinear Amplifier

The loop gain equations are derived by considering a signal going through the loop, arriving back at the input, and subtracting from the input. In Fig. 4, the nonlinearity in the forward branch is represented by its cross-power operator G and the harmonic distortion signal θ_h with power ϕ_{hh} (λ). At the subtractor, $\theta_i-F\theta_0$ equals θ_e, and cross powers to the input are

$$\phi_{ie}=\frac{\phi_{io}}{G}=\phi_{ii}-F_{io} \quad (39)$$

since θ_h does not correlate with θ_i. Solving for ϕ_{io} yields

$$\phi_{io}=\frac{G}{1+FG}\phi_{ii} \quad (40)$$

The equivalent closed-loop transference is a function only of the cross-power operators G and F. For a nonlinearity, the cross-power operator is given by equation 31 as (N_1/σ). This could be thought of as a "linearization" for Gaussian signals, or as the "gain" of a nonlinearity.

If ϕ_{hh} is the harmonic power appearing at the output when the loop is open, and if it is tested at the normal operating power levels and probability distributions, then closing the loop will cause the harmonic component of the output cross-power to be

$$\phi_{ho}=\frac{1}{1+FG}\phi_{hh} \quad (41)$$

The output self-power due to the input is

$$\frac{G}{1+FG}\overline{\frac{G}{1+FG}}\phi_{ii}(\lambda) \quad (42A)$$

The bar above the operator means the complex conjugate as a function of the variable $\lambda=\omega+ja$.

The output self-power due to the harmonic generation is

$$\frac{1}{1+FG}\overline{\frac{1}{1+FG}}\phi_{hh}(\lambda) \quad (42B)$$

The total output power is the sum of equations 42(A) and (B).

$$\phi_{oo}=\frac{1}{(1+FG)\overline{(1+FG)}}(\bar{G}\bar{G}\phi_{ii}+\phi_{hh}) \quad (42C)$$

The transferences must be evaluated for the case when the nonlinearity receives a probability distribution which is the same as that produced by the signal plus the harmonic distortion, as it appears going through the loop.

Error Power Due to a Nonlinearity

An amplifier which is supposed to have a gain of n_1 may have a saturation curve which is describable by a power series. The error voltage θ_e at the output will be the input times a linear constant gain of n_1, minus the output of a power-series nonlinearity. The error autocorrelation is

$$\psi_{ec}=n_1^2\psi_{ii}-n_1\psi_{io}-n_1\psi_{oi}+\psi_{oo} \quad (43)$$

Collect the terms with the same spectrum as the input.

$$\psi_{ee}=n_1^2\sigma^2\rho-2n_1\sigma N_1\rho+N_1^2\rho+\left[N_0^2+\frac{\rho^2}{2!}N_2^2+\frac{\rho^3}{3!}N_3^2+\ldots\right] \quad (44A)$$

$$\psi_{ee}=\rho(N_1-n_1\sigma)^2+\left[N_0^2+\frac{\rho^2}{2!}N_2^2+\frac{\rho^3}{3!}N_3^2+.\right] \quad (44B)$$

The error power in volts squared follows directly by substituting τ equals zero, ρ equals one.

$$\psi_{ee}(0)=(n_3c_3\sigma^3+n_5c_5\sigma^5+\ldots)^2+\left[N_0^2+\frac{N_2^2}{2!}+\frac{N_3^2}{3!}+\ldots\right] \quad (45)$$

The second bracket is all harmonic power; the first is error power due to the change in gain from n_1 to N_1/σ.

In case the nonlinearity has only cubic distortion, the error power is $5(n_3c_3\sigma^3)^{2/3}$ volts squared. In case it has only square

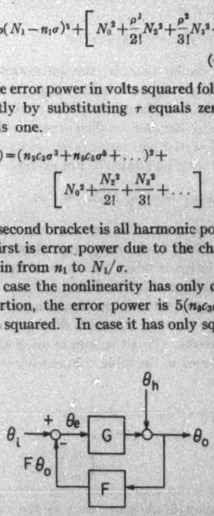

Fig. 4. Nonlinearity in forward branch of feedback system represented as linear transference G and harmonic power input θ_h

Vol.
Pt. 1
1959

distortion, the error power is $3(n_2\sigma^2)^2$ volts squared, part of which is direct current due to rectification.

In equation 32, the equivalent nonlinear gain is given as N_1/σ. If the error power at the output of a nonlinearity is computed with respect to a linear branch with gain of N_1/σ, then the coefficient of the first power of ρ in the foregoing is zero, and the error power is

$$\psi_{ee}(0)=\left[N_0^2+\frac{N_2^2}{2!}+\frac{N_3^2}{3!}+\ldots\right] \tag{46}$$

If one minimizes the error power between the outputs of a nonlinearity and a linear variable gain device, he arrives at the foregoing error power, corresponding to a linear gain setting of N_1/σ.

Filtering Effect of Nonlinearities and Linearities

A Gaussian signal going through a linear filter is still Gaussian when it emerges from the output. If a non-Gaussian signal is passed through several filters, so that the output power is markedly reduced owing to the reduction in bandwidth, the resulting signal is much nearer gaussian, and as the bandwidth approaches zero, the distribution approaches a Gaussian one. In general, then, if a nonlinearity occurs in or after the high gain in a control system, the subsequent filtering of the harmonics (due to the closed loop characteristics), before they reach the output, will change their distribution to an almost Gaussian one. The power spectrum of the harmonics at any point in the system beyond the nonlinearity can be determined by starting with the Fourier transform of equation 36, and operating on it with the linear transferences of the successive linear members. Because of the filtering action, it is usually permissible to determine nonlinear transferences for the assumption of a Gaussian input.

If the nonlinearity definitely receives a non-Gaussian signal, there are two approaches to the problem. One is to measure the crosspower on the actual equipment as a function of different input levels. The other is to break up the input signal into an equivalent Gaussian signal and a nonlinear operator; the latter approach will be discussed in a subsequent section.

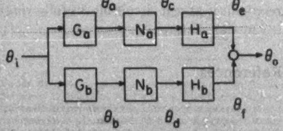

Fig. 5. Sum of two signals from parallel branches with nonlinearities N_a and N_b imbedded between linear filters

A nonlinearity is an amplitude filter. As such, it changes both the distribution and the spectrum. If the filter selects a narrow band of amplitudes, the output looks like a random sequence of step functions. The ultimate in narrow-band amplitude filtering is a probability density distribution with delta functions at only two amplitude values. This approaches the single time constant spectrum of clipped thermal noise. The time constant is zero if the thermal noise has infinite bandwidth. In other words, a flat spectrum into a narrow-band amplitude filter emerges as a flat spectrum. In general, because of the harmonic generation of a nonlinearity, a narrow spectrum input will have considerable energy removed from the spectrum and reintroduced at higher frequencies. This usually makes the output spectrum much flatter than the input.

As a general rule, linear filters tend to produce a Gaussian amplitude distribution, and a "peaked" power spectrum. Nonlinearities tend to produce a "flat" power spectrum and peaked amplitude distribution. If the nonlinear peaking of a Gaussian amplitude distribution occurs along the skirts of the curve, it may at first sight appear like a flattening of the center.

Multiple Nonlinearities

If two nonlinearities are placed in parallel, the corresponding n's of each should be added for use in equations 31 through 37. Since the N's are additive combinations of the n's, they too may be added. If in Fig. 5 all the G's and H's are unity

$$\theta_o=\theta_{ao}+\theta_{bo} \tag{47}$$

$$\theta_{ao}=n_{a1}\theta_i+n_{a2}\theta_i^2+n_{a3}\theta_i^3+\ldots$$

$$\theta_{bo}=n_{b1}\theta_i+n_{b1}\theta_i^2+n_{b3}\theta_i^3+\ldots \tag{48}$$

$$N_1=N_{a1}+N_{b1}$$

$$N_2=N_{a2}+N_{b2},\ \text{etc!} \tag{49}$$

Fig. 5 shows two nonlinearities in parallel branches, but isolated from each other by linear dynamic elements G and H.

The output power and cross power of this circuit can be written, with the caution that higher harmonics of the nonlinearities are correlated with each other.

The cross power is the sum of the cross powers of each branch:

$$\phi_{io}(\lambda)=H_a\left(\frac{N_{a1}}{\sigma_a}\right)G_a\phi_{ii}+H_b\left(\frac{N_{1b}}{\sigma_b}\right)$$
$$G_b\phi_{ii}=\left(\frac{H_aG_aN_{a1}}{\sigma_a}+\frac{H_bG_bN_{b1}}{\sigma_b}\right)\phi_{ii}(\lambda) \tag{50}$$

The transference has all the poles of all of the linear elements, but the zeros are amplitude-sensitive.

The first step toward obtaining the output power is to write the cross power between θ_a and θ_b.

$$\phi_{ab}=\bar{G}_aG_b\phi_{ii} \tag{51}$$

The normalized CC is

$$\rho_{ab}(\tau)=\frac{\psi_{ab}(\tau)}{\sigma_a\sigma_b}=\frac{\mathfrak{F}^{-1}\bar{G}_aG_b\phi_{ii}(\lambda)}{\sigma_a\sigma_b} \tag{52}$$

The CC between θ_c and θ_d is given by Tables I and II. Each term in these tables is the correlation between the mth power of θ_a and the nth power of θ_b. Each term should therefore be multiplied by the appropriate coefficients in N_a and N_b, namely, $n_{am}n_{bn}$.

The CC ψ_{cd} is the sum of all terms in these tables in the form of $n_{am}n_{bn}\psi_{ambn}$. Each term contains the product $\sigma_a{}^m\sigma_b{}^n$. Therefore, in the sum, one need only attach the coefficient n_{am} to each $\sigma_a{}^m$, and the coefficient n_{bn} to each $\sigma_b{}^n$. All terms in the table are added together, and coefficients of the powers of ρ collected together. When this is done and the coefficients are identified, they have the following simple form:

$$\psi_{cd}=N_{ao}N_{bo}+\rho_{ab}N_{a1}N_{b1}+\rho_{ab}{}^2\frac{N_{a2}N_{b2}}{2!}+$$
$$\rho_{ab}{}^3\frac{N_{a3}N_{b3}}{3!}+\rho_{ab}{}^4\frac{N_{a4}N_{b4}}{4!}+\ldots \tag{53}$$

The N's are given by equations 34 and 35, for zero average input. They are the same N's that are used for the autocorrelation at points c and d.

$$\psi_{cc}=N_{ao}{}^2+\rho_{aa}N_{a1}{}^2+\rho_{aa}{}^2\frac{N_{a2}{}^2}{2!}+$$
$$\rho_{aa}{}^3\frac{N_{a3}{}^2}{3!}+\ldots \tag{54}$$

The output power spectrum of the sum of the two parallel branches in Fig. 5 is

$$\phi_{oo}=H_aH_a\mathfrak{F}\psi_{cc}+H_bH_b\mathfrak{F}\psi_{dd}+$$
$$H_aH_b\mathfrak{F}\psi_{cd}+H_bH_a\mathfrak{F}\psi_{dc} \tag{55}$$

When two nonlinearities are placed in series, the resultant n's are given by the substitution of the first signal polynomial into the second. The order of power flow is quite important.

In Fig. 6(A)

$$\theta_b=n_{a1}\theta_i+n_{a2}\theta_i^2+n_{a3}\theta_i^3+\ldots \tag{56}$$

$$\theta_o=n_{b1}\theta_b+n_{b2}\theta_b^2+n_{b3}\theta_b^3+\ldots \tag{57}$$

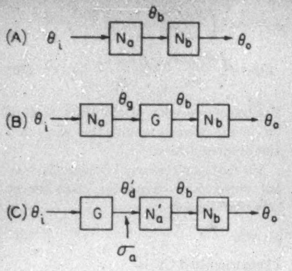

Fig. 6. Systems with nonlinearities in series. A—One nonlinearity immediately following another without filtering: can be combined directly. B—Linear dynamic filter following one nonlinearity and preceding another. C—Transformation of (B) by moving linear filter to input so that two resultant nonlinearities can be combined

Substituting and collecting terms yields

$$\theta_o=\theta_i(n_{b1}n_{a1})+\theta_i^2(n_{b1}n_{a2}+n_{b2}n_{a1}^2)+ \theta_i^3(n_{b1}n_{a3}+n_{b2}(2n_{a1}n_{a2})+n_{b3}n_{a1}^3)+ \theta_i^4[n_{b1}n_{a4}+n_{b2}(n_{a2}^2+2n_{a1}n_{a3})+ n_{b3}(3n_{a1}^2n_{a2})+n_{b4}n_{a1}^4]+\theta_i^5[n_{b1}n_{a5}+ n_{b2}(2n_{a1}n_{a4}+2n_{a2}n_{a3})+n_{b3}(3n_{a1}n_{a2}^2+ 3n_{a1}^2n_{a3})+n_{b4}(4n_{a1}^3n_{a2})+n_{b5}n_{a1}^5]+ \theta_i^6[n_{b1}n_{a6}+n_{b2}(n_{a3}^2+2n_{a1}n_{a5}+ 2n_{a2}n_{a4})+n_{b3}(n_{a2}^3+3n_{a1}^2n_{a4})+ n_{b4}(6n_{a1}^2n_{a2}^2+4n_{a1}^3n_{a3})+ n_{b5}(5n_{a1}^4n_{a2})+n_{b6}n_{a1}^6]+\ldots \quad (58)$$

Therefore n_{c1} is $n_{b1}n_{a1}$; n_{c2} is $(n_{b1}n_{a1}^2+n_{b1}n_{a2})$; etc. Using the N_c coefficients eliminates the necessity of computing the rms value σ_b.

When two nonlinearities are separated by a linear element as in Fig. 6(B), the cross power is not much more difficult, but the self-power is. For the case of a d-c level change at θ_g (so that both nonlinearities receive zero average input) and the assumption of sufficient filtering (so that the inputs to both nonlinearities are Gaussian),

$$\phi_{io}=\left(\frac{N_{b1}}{\sigma_b}\right)G\left(\frac{N_{a1}}{\sigma_a}\right)\phi_{ii} \quad (59)$$

$$\phi_{gg}=\mathfrak{F}\left[\left(\frac{N_{a1}}{\sigma_a}\right)^2\psi_{ii}+\left(\frac{N_{a2}}{\sigma_a^2}\right)^2\frac{\psi_{ii}^2}{2!}+ \left(\frac{N_{a3}}{\sigma_a^3}\right)\frac{\psi_{ii}^3}{3!}+\ldots \quad (60)$$

$$\psi_{oo}=\left(\frac{N_{b1}}{\sigma_b}\right)^2\mathfrak{F}^{-1}G\bar{G}\phi_{gg})+\left(\frac{N_b^2}{\sigma_b^2}\right)^2\times \frac{(\mathfrak{F}^{-1}G\bar{G}\phi_{gg})^2}{2!}+\left(\frac{N_{b3}}{\sigma_b^3}\right)^2\frac{(\mathfrak{F}^{-1}G\bar{G}\phi_{gg})^3}{3!}+ \ldots \quad (61)$$

If G provides so little filtering that the input to the second nonlinearity cannot be considered Gaussian, then the circuit in Fig. 6(B) should be converted to the arrangement of Fig. 6(C). To derive the N_a' operator, consider that there are correction factors on the n_a coefficients to account for the attenuation due to G. First, put G ahead of N_a. Next, solve for ϕ_{aa}, ψ_{aa}, σ_a, and ρ_a. Write separately the power output at θ_b for each term in the nonlinearity N_a', and set each equal to the old power output for the term of the same order. For example, the cube has

$$\psi_b'(\tau)=(n_{a3}'c_3\sigma_a^3)^2\rho_a(\tau)+ (2n_{a3}'c_{3a}\sigma^3)^2\frac{\rho_a^3(\tau)}{3!} \quad (62)$$

The previous value was

$$\psi_b(\tau)=(n_{a3}c_3\sigma_i^3)^2\rho_0(\tau)+ (2n_{a3}c_3\sigma_i^3)^2\frac{\rho_i^3(\tau)}{3!} \quad (63)$$

Setting these equal for τ of zero yields

$$n_{a3}'\sigma_a^3=n_{a3}\sigma_i^3 \quad (64)$$

In a similar manner, every n coefficient will be increased by the corresponding power of the ratio of the old to the new rms input of N_a. But note that since every n coefficient appears only times the corresponding power of σ, the values of N_{a1}', N_{a2}', N_{a3}', etc., are identical to the old values of N_{a1}, N_{a2}, N_{a3}, etc., based on σ_i.

In a similar manner, it can be shown that using the identical nonlinear transference as before will yield the correct cross powers (watts, not spectrum) and correct total output power. It does not give the correct power spectrum or the autocorrelation and, consequently, the output of the following filter or nonlinearity will not be correct. The rule for moving a linear filter from a position following a nonlinearity to a position head of it, is to change their positions without any change in the linear transference, and with the N's of the nonlinear transference based on its old rms input, (σ_i), operating on its new spectral input (ψ_{aa}'/σ_a). From this new form, the new nonlinear coefficients can be combined with those of N_b in Fig. 6(C), with the use of equation 58, to obtain an over-all single nonlinear transference.

Non-Gaussian Distributions

The response of smooth nonlinearities to Gaussian signals has been analyzed. The equivalent linear gain, the cross-power spectrum operator, and the output self-power spectrum can all be obtained easily. An approximation to the response to non-Gaussian distributions can be obtained by describing the input signal in terms of the mechanism by which it could be made. In Fig. 6(B), the signal θ_b is non-Gaussian owing to the harmonic generation of N_a. This signal could be described accurately in terms of the mechanism of N_a followed by G. However, for convenience in using the description to calculate actual responses, the circuit of Fig. 6(C) is preferable. Placing G first, followed by the nonlinearity N_a' as a signal description, permits the immediate combination of the nonlinear terms in the signal with the nonlinear terms in the circuit. Exactly this is done in linear analysis when a signal is described by its Laplace transform, so that it can be combined with the Laplace transform of the linear circuit, to obtain the transform of the output. The signal and the circuit are both described in the same language, by a pattern of poles and zeros in the s plane.

Here, both the signal and the circuit must be described in the same language, in this case by N operators. The signal description then takes the form of equation 36, where its measured autocorrelation function is expanded in a power series of an autocorrelation function that has no beat frequencies. Notice that the terms of equation 38 can be identified as the beat frequencies and harmonics of a fundamental correlation. When harmonic terms like these are apparent in a measured autocorrelation, a series like equation 36 should be chosen, and by setting corresponding terms equal, the values of Ψ_{ii}/σ_i and N_1, N_2, N_3, etc., may be determined. From the N's, the n's may be obtained algebraically. The signal may now be considered an original Gaussian distribution, tailored first by a linear filter G, and second by a power series N_a'; see Fig. 6(C). The block representing the nonlinear part of the signal may be combined with the circuit nonlinearity with the use of equation 58, and the output of the combination obtained directly from the known Gaussian input.

Whenever possible, a signal description should be in the same kind of mathematics as the circuit description. For a random signal, the best method is to represent it as real circuit blocks following a Gaussian, flat, random source.

Spectral Output of Piecewise Linear Nonlinearity

OTTO J. M. SMITH
MEMBER AIEE

THE TRANSFERENCE or effective gain of a piecewise linear component is derived. The output autocorrelation function of a clipper, a dead zone, and a general piecewise linear nondynamic component is obtained by a double integration of the second probability density. The output power is a sum of Gaussian error integrals. This can be divided into fundamental or correlated power, and distortion power due to lack of desired signal or presence of harmonics.

Saturation or Clipping

A large class of nonlinearities includes those with sharp discontinuities in the output-input relationship. In this class are dead zone, saturation, and the approximations to any nonlinear curve by a sequence of straight-line segments. The last-mentioned may be thought of as the sum of several dead zones and saturations. The cross-power transferences and output power operators will be derived for these nonlinearities by a double integration of the second probability density. This method has also been applied to power series nonlinearities.[1–6] An output transducer can only deliver a finite maximum power or torque. The error power due to this "clipping" or saturation should be balanced against the cost of the transducer to obtain the best compromise. The output error as a function of the clipping level for random signals will be derived.

The input-output relation of a saturating element is shown in Fig. 1(A), where θ is the output variable, and x is the input variable. The proportional region has unity slope; k is the clipping level in terms of the input. Mathematically, the output is

$$\begin{aligned}\theta(x)&=k,\ k<x\\ \theta(x)&=x,\ -k<x<k\\ \theta(x)&=-k,\ x<-k\end{aligned}\tag{1}$$

The cross correlation (CC) between input and output is the double integral over all values of the input and output of the product of the input, times the output, times the second (joint) probability density.

$$\psi_{io}(\tau)=\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}w\theta(x)\left(\frac{\partial p}{\partial w}\,\frac{\partial p}{\partial x}\right)dwdx\tag{2}$$

The second probability density for a Gaussian input is given by

$$\left(\frac{\partial p}{\partial w}\,\frac{\partial p}{\partial x}\right)=\frac{1}{2\pi\sigma^2\sqrt{1-\rho^2}}\times \exp\left(-\frac{w^2-2\rho wx+x^2}{2(1-\rho^2)\sigma^2}\right)\tag{3}$$

where σ is the rms value of the input and $\rho(\tau)$ is the normalized autocorrelation equal to $\psi_{ii}(\tau)/\sigma^2$. With the following change of variable, the exponent will appear as a complete square, and the integral with respect to u can be obtained immediately:

$$z=\frac{x}{\sigma}\tag{4}$$

$$u=\frac{\frac{w}{\sigma}-\rho\frac{x}{\sigma}}{\sqrt{2}\sqrt{1-\rho^2}}\tag{5}$$

$$\psi_{io}(\tau)=\frac{\sigma^2\sqrt{1-\rho^2}}{\pi}\int_{-\infty}^{+\infty}\frac{\theta(z)}{\sigma}\epsilon^{-\frac{z^2}{2}}\times dz\int_{-\infty}^{\infty}\left(u+\frac{\rho z}{\sqrt{2}\sqrt{1-\rho^2}}\epsilon^{-u^2}\right)du\tag{6}$$

Performing the last integration yields

$$\psi_{io}(\tau)=\frac{\sigma^2\rho(\tau)}{\sqrt{2\pi}}\int_{-\infty}^{+\infty}\frac{\theta(z)}{\sigma}\times z\epsilon^{-\frac{z^2}{2}}dz\tag{7}$$

In equation 7, notice that all functions of time have come outside of the integral.

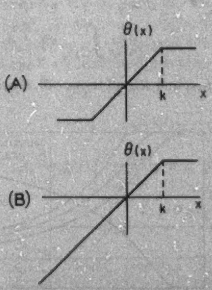

Fig. 1. Input-output relation of clipper or saturating component

A—Symmetrical
B—Single-sided clipping

Paper 59-264, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted December 30, 1957; made available for printing December 17, 1958.

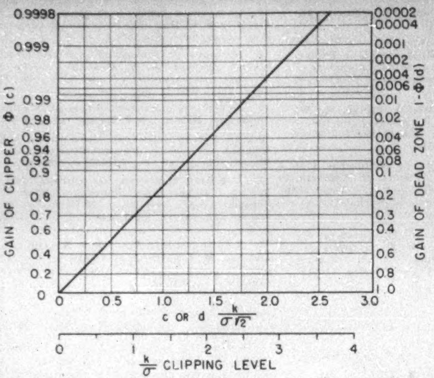

Fig. 2. Statistical gain of symmetrical clipper and of symmetrical dead zone as function of ratio of clipping level to rms signal

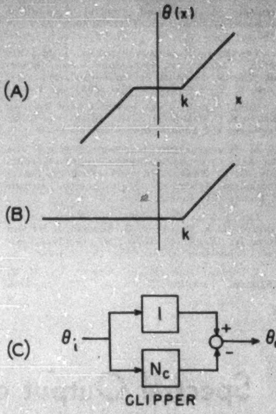

Fig. 4. Dead zone. A—Input-output relation for symmetrical dead zone. B—One-sided dead zone. C—Exact equivalent circuit for dead zone

This can therefore be considered a complete general equation for the calculation of the CC of any nondynamic function with Gaussian input. The Fourier transform can be taken before integrating. The transference then becomes only an amplitude-dependent gain term, for any kind of nondynamic nonlinearity. The cross-power spectrum is

$$\phi_{io}(\omega)=\phi_{ii}(\omega)\times\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty}\frac{\theta(z)}{\sigma}z\epsilon^{-\frac{z^2}{2}}\,dz \tag{8}$$

where z is the normalized input signal.

For the case of symmetrical clipping, $\theta(z)/\sigma$ equals z between values of z of $\pm k/\sigma$, and equals k/σ outside of this range. Therefore, when these values are substituted, the transference is

$$\frac{\phi_{io}}{\phi_{ii}}=\frac{k}{\sigma\sqrt{2\pi}}\int_{-\infty}^{-k/\sigma}\epsilon^{-\frac{z^2}{2}}z\,dz+\frac{k}{\sigma\sqrt{2\pi}}\int_{+k/\sigma}^{+\infty}\epsilon^{-\frac{z^2}{2}}z\,dz+\frac{1}{\sqrt{2\pi}}\int_{-k/\sigma}^{+k/\sigma}z^2\epsilon^{-\frac{z^2}{2}}\,dz \tag{9}$$

The first and second terms cancel because the first term is a negative area, and the second an equal positive area.

Integrating the last term by parts yields

$$\frac{\phi_{io}(\omega)}{\phi_{ii}(\omega)}=\frac{1}{\sqrt{2\pi}}\left[-z\epsilon^{-\frac{z^2}{2}}\right]_{-k/\sigma}^{+k/\sigma}+\frac{1}{\sqrt{2\pi}}\int_{-k/\sigma}^{+k/\sigma}\epsilon^{-\frac{z^2}{2}}\,dz=\Phi\left(\frac{k}{\sigma\sqrt{2}}\right) \tag{10}$$

$\Phi(x)$ is defined as the Gaussian error integral or probability integral:

$$\Phi(x)=\frac{2}{\sqrt{\pi}}\int_0^x\epsilon^{-u^2}\,du \tag{11}$$

This is an important fundamental result. It states that the transference of a symmetrical clipper is a cross-power operator equal to the probability integral of a kind of normalized clipping level. The peak value of the clipping level is k.

Consider $\sqrt{2}\sigma$ as an "equivalent" peak input signal. Then the ratio of the clipping voltage to the equivalent peak input, or the ratio of the "effective" clipping voltage $k/\sqrt{2}$ to the effective or rms input voltage, is defined as the normalized clipping level c.

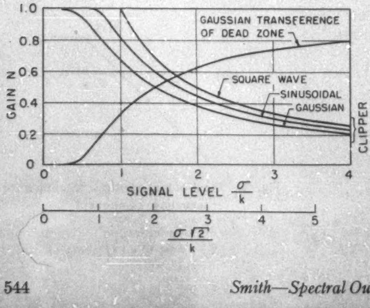

Fig. 3. Gain of clipper as function of type of input signal. For random Gaussian input, statistical gain is ratio of cross-power spectrum to input power spectrum. For analytical functions, fundamental harmonic component gain is shown

$$c=\frac{k}{\sigma\sqrt{2}} \tag{12}$$

The spectral transference is the Gaussian error integral of c. Since the clipping transference is not a time function, it is equally applicable to CCs as well as to cross powers.

$$\psi_{io}(\tau)=\Phi(c)\psi_{ii}(\tau) \tag{13}$$

This transference is plotted in Figs. 2 and 3 as a function of clipping level and signal level respectively. It can be considered a nondynamic amplitude-dependent gain term for the calculation of loop gain for stability studies. The component of the output power which correlates with the input is

$$\Phi^2(c)\psi_{ii}(0)=\sigma^2\Phi^2(c)\text{ watts} \tag{14}$$

There are, in addition, a number of harmonic power components, which will be derived later.

Fig. 1(B) shows an unsymmetrical clipper. To obtain its transference, change the lower limit of the last integral in equation 9 to $-\infty$, and omit the first integral. The unsymmetrical transference then becomes

$$\frac{\phi_{io}}{\phi_{ii}}=\frac{1}{2}+\frac{1}{2}\Phi(c) \tag{15}$$

Dead Zone

A dead zone component is exactly the same as one minus a clipping component; see Fig. 4. The cross-power transference and CC for a symmetrical dead zone are therefore

Vol.
Pt. 1
1959

$$\frac{\phi_{io}(\omega)}{\phi_{ii}(\omega)}=\frac{\psi_{io}(\tau)}{\psi_{ii}(\tau)}=1-\Phi\left(\frac{k}{\sigma\sqrt{2}}\right)=1-\Phi(d) \qquad (16)$$

A normalized dead zone d is defined as 0.707 times the peak dead zone in one direction divided by the rms input. This is true of a symmetrical dead zone with a Gaussian input. The dead-zone gain is also shown in Figs. 2 and 3. Notice that the additive relationship between the dead-zone transferences and the clipping transference, which is apparent for periodic inputs, also holds for random inputs.

An unsymmetrical dead zone is shown in Fig. 4(B). Its transference is exactly one minus that for an unsymmetrical clipper:

$$\frac{\phi_{io}(\omega)}{\phi_{ii}(\omega)}=\frac{1}{2}-\frac{1}{2}\Phi(d) \qquad (17)$$

General Discontinuous-Slope Nonlinearity

A large class of nonlinearities can be represented by straight-line segments for the input-output relationship. The transference of complicated devices can be written down immediately with the tools just derived. The symmetrical curve in Fig. 5(A) is the sum of a linear function and several dead zones.

At each point where the slope changes, the new dead-zone term contributes the change in slope. For abbreviation, slopes will be designated by m, the tangent of the angle, and probability integrals by

$$\Phi_3\equiv\Phi(d_3) \qquad (18)$$

The gain is

$$\frac{\phi_{io}}{\phi_{ii}}=m_1+(m_2-m_1)(1-\Phi_1)+ (m_3-m_2)(1-\Phi_2)+(m_4-m_3)(1-\Phi_3)+\ldots \qquad (19)$$

$$\frac{\phi_{io}}{\phi_{ii}}=m_1\Phi_1+m_2(\Phi_2-\Phi_1)+m_3(\Phi_3-\Phi_2)+\ldots \qquad (20)$$

The gain is the sum of each slope times the difference of the normal probability integrals for each end of the straight line.

The unsymmetrical curve in Fig. 5(B) is the sum of unsymmetrical dead zones with gains like those indicated in equation 17.

$$\frac{\phi_{io}}{\phi_{ii}}=\frac{m_1}{2}(1-\Phi_0)+\frac{m_2-m_1}{2}(1-\Phi_1)+ \frac{m_3-m_2}{2}(1-\Phi_2)+\ldots+ \frac{m_a}{2}(1-\Phi_0)+\frac{m_b-m_a}{2}(1-\Phi_a)+ \frac{m_c-m_b}{2}(1-\Phi_b)+\ldots \qquad (21)$$

$$=\frac{1}{2}[m_1(\Phi_1-\Phi_0)+m_2(\Phi_2-\Phi_1)+ m_3(\Phi_3-\Phi_2)+\ldots+m_a(\Phi_a-\Phi_0)+ m_b(\Phi_b-\Phi_a)+m_c(\Phi_c-\Phi_b)+\ldots] \qquad (22)$$

Again, the gain is the sum of each slope times the difference of the normal probability integrals for each end of the straight line. It is given a weighting of one half if the slope appears on only one side of the origin, and a weighting of one if it appears symmetrically on both sides. This method permits one to evaluate the gain of a combination of spring-returned backlash and saturation in a control loop, and to specify the range of Gaussian input signals for which the control would be satisfactory.

Output Power of Discontinuous-Slope Nonlinearity

The two kinds of errors due to a clipper are: 1. the desired signal that is not permitted to reach the output; and 2. extra distortion power in the output that should not be there. The magnitudes of these two components will be derived.

To obtain the harmonic power and the power of a nonlinearity or the sum of several nonlinearities, one needs the cross-power between the outputs of two different elements. Consider N_1 and N_2, which are two discontinuous-slope nonlinearities with Gaussian inputs a and b respectively, and with a normalized cross correlation of $\rho_{ab}(\tau)$ between the inputs. The output signals are θ_1 and θ_2 respectively. The CC between the outputs is

$$\psi_{12}=\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\theta_1\theta_2\left(\frac{\partial p}{\partial w}\,\frac{\partial p}{\partial x}\right)dw\,dx \qquad (23)$$

where the second probability density is defined by equation 24:

$$\left(\frac{\partial p}{\partial w},\,\frac{\partial p}{\partial x}\right)=\frac{1}{2\pi\sigma_a\sigma_b\sqrt{1-\rho_{ab}^2}}\times \exp\left\{-\frac{1}{2(1-\rho_{ab}^2)}\left[\left(\frac{w}{\sigma_a}\right)^2- 2\rho_{ab}\left(\frac{w}{\sigma_a}\right)\left(\frac{x}{\sigma_b}\right)+\left(\frac{x}{\sigma_b}\right)^2\right]\right\} \qquad (24)$$

Let

$$z=x/\sigma_b \qquad (25)$$

and

$$u=\frac{\left(\dfrac{w}{\sigma_a}-\rho_{ab}^2\right)}{\sqrt{2}\sqrt{1-\rho_{ab}^2}} \qquad (26)$$

Substituting this change of variable into equation 24, and then substituting the density into equation 23, causes the CC to become

$$\psi_{12}=\frac{\sigma_a\sigma_b}{\sqrt{2}\pi}\int_{-\infty}^{+\infty}\frac{\theta_2}{\sigma_b}\,\epsilon^{-\frac{z^2}{2}}\times dz\int_{-\infty}^{+\infty}\frac{\theta_1}{\sigma_a}\,\epsilon^{-u^2}\,du \qquad (27)$$

If N_1 is a symmetrical clipper, θ_1, is w between $-u'$ of $(-c_1-\rho z/\sqrt{2})/\sqrt{1-\rho^2}$, and $+u''$ of $(+c_1-\rho z/\sqrt{2})/\sqrt{1-\rho^2}$, where c_1 is $k_1/\sigma a\sqrt{2}$. The term θ_1 is $-k_1$ below the lower limit, and $+k_1$ above the upper limit.

$$\int_{-\infty}^{+\infty}\frac{\theta_1}{\sigma_a}\,\epsilon^{-u^2}\,du=\int_{-u'}^{+u''}(\sqrt{2}\sqrt{1-\rho^2}\,u+ \rho z)\epsilon^{-u^2}\,du+\int_{-\infty}^{u'}\frac{-k_1}{\sigma_a}\epsilon^{-u^2}\,du+ \int_{+u''}^{+\infty}\frac{k_1}{\sigma_a}\,\epsilon^{-u^2}\,du \qquad (28)$$

$$=\frac{+\sqrt{1-\rho^2}}{\sqrt{2}}(\epsilon^{-(-u')^2}-\epsilon^{-(u'')^2})+ \frac{\rho z\sqrt{\pi}}{2}[\Phi(u'')-\Phi(-u')]+ c_1\sqrt{\frac{\pi}{2}}[2-\Phi(u'')+\Phi(-u')] \qquad (29)$$

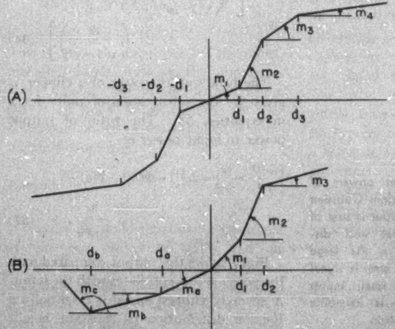

Fig. 5. General nonlinearity represented by straight-line segments. A—Symmetrical about origin. B—Unsymmetrical. Slopes m can be negative, and nonlinearity can have several maxima and minima

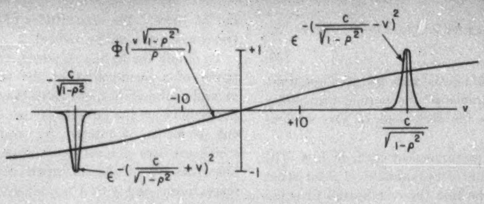

Fig. 6. Components whose product must be integrated to obtain output autocorrelation of discontinuous-slope nonlinearity

The result of the first integration in the foregoing may be substituted into equation 27. Each term must be integrated by parts, and there will be one integral left over. For the particular case when the clipping levels are identical, and a and b are the same, this will yield the output autocorrelation. Divided by the input power, it is

$$\frac{\psi_{oo}(\tau)}{\sigma_i^2}=2c^2[1-\Phi(c)]+\left[\Phi\left(\frac{c(1+\rho)}{\sqrt{1-\rho^2}}\right)+\Phi\left(\frac{c(1-\rho)}{\sqrt{1-\rho^2}}\right)\right]\times\left[+\left(\frac{\rho}{2}+c^2\right)\Phi(c)-\frac{3\rho c}{2\sqrt{\pi}}\epsilon^{-c^2}\right]+\left[\Phi\left(\frac{c(1-\rho)}{\sqrt{1-\rho^2}}\right)-\Phi\left(\frac{c(1+\rho)}{\sqrt{1-\rho^2}}\right)\right]\times\left[\frac{c(1-\rho^2)}{\sqrt{\pi}}\epsilon^{-c^2}\right]-\frac{\rho c^2}{\sqrt{2}\sqrt{1-\rho^2}}\times\int_{-\infty}^{k/\sigma}(\epsilon^{-(u'')^2}-\epsilon^{-(u')^2})\Phi\left(\frac{z}{\sqrt{2}}\right)dz-\frac{\rho c^2}{\sqrt{2\pi}\sqrt{1-\rho^2}}\int_{-k/\sigma}^{+\infty}(\epsilon^{-(u'')^2}-\epsilon^{(-u')^2})\Phi\left(\frac{z}{\sqrt{2}}\right)dz+\frac{\rho}{2\sqrt{2\pi}\sqrt{1-\rho^2}}\int_{+k/\sigma}^{k/\sigma}(\epsilon^{-(u'')^2}-\epsilon^{-(u')^2})\Phi\left(\frac{z}{\sqrt{2}}\right)dz \quad (30)$$

The derivation of equation 30 is quite tedious, although straightforward. The integration of the last terms will be shown only for the case when ρ is near unity, i.e., for a calculation of output power.

The variable must be changed to

$$v=\frac{\rho z}{\sqrt{1-\rho^2}\sqrt{2}} \quad (31)$$

$$u'=\frac{1}{\sqrt{1-\rho^2}}+v;\ u''=\frac{1}{\sqrt{1-\rho^2}}-v \quad (32)$$

The last term in the autocorrelation becomes

$$\frac{1}{2\sqrt{\pi}}\int_{-\frac{c}{\sqrt{1-\rho^2}}}^{\frac{c}{\sqrt{1-\rho^2}}}\left[\epsilon^{-\left(\frac{c}{\sqrt{1-\rho^2}}-v\right)^2}-\epsilon^{-\left(\frac{c}{\sqrt{1-\rho^2}}+v\right)^2}\right]\Phi\left(\frac{\sqrt{1-\rho^2}}{\rho}v\right)dv \quad (33)$$

Fig. 6 shows these functions plotted. The integral goes from the center line of one exponential peak to the center line of the other. All of the significant area is concentrated around these lines. The probability integral acts like a constant-weighting function across the peak, and makes both areas positive. Since there is essentially no area contribution in the regions where Φ is changing, Φ may be assumed to be constant at $+\Phi(c/\rho)$ for positive v, and the same negative value for negative v. Removing this constant outside of the integral, changing the sign for the negative integration, and then writing twice the positive integration for the sum of the two equal areas, yields, for the last integral in equation 30

$$-\frac{1}{2}\Phi\left(\frac{c}{\rho}\right)\left[\Phi\left(\frac{c}{\sqrt{1-\rho^2}}-v\right)+\Phi\left(\frac{c}{\sqrt{1-\rho^2}}+v\right)\right]_0^{\frac{c}{\sqrt{1-\rho^2}}}=\Phi\left(\frac{c}{\rho}\right)\left[\Phi\left(\frac{c}{\sqrt{1-\rho^2}}\right)-\frac{1}{2}\Phi\left(\frac{2c}{\sqrt{1-\rho^2}}\right)\right] \quad (34)$$

In a similar manner, the sum of the other two integrals in equation 30 becomes

$$+c^2\Phi\left(\frac{c}{\rho}\right)\left[\Phi\left(\frac{c}{\sqrt{1-\rho^2}}-v\right)+\Phi\left(\frac{c}{\sqrt{1-\rho^2}}+v\right)\right]_{\frac{c}{\sqrt{1-\rho^2}}}^{\frac{\infty}{\sqrt{1-\rho^2}}}=-c^2\Phi\left(\frac{c}{\rho}\right)\Phi\left(\frac{2c}{\sqrt{1-\rho^2}}\right) \quad (35)$$

The normalized output autocorrelation of a symmetrical clipper is therefore

$$\frac{\psi_{oo}(\tau)}{\sigma_i^2}=2c^2[1-\Phi(c)]+\left[\Phi\left(\frac{c(1-\rho)}{\sqrt{1-\rho^2}}\right)+\Phi\left(\frac{c(1+\rho)}{\sqrt{1-\rho^2}}\right)\right]\times\left[\left(\frac{\rho}{2}+c^2\right)\Phi(c)-\frac{3\rho c}{2\sqrt{\pi}}\epsilon^{-c^2}\right]+\left[\Phi\left(\frac{c(1-\rho)}{\sqrt{1-\rho^2}}\right)-\Phi\left(\frac{c(1+\rho)}{\sqrt{1-\rho^2}}\right)\right]\times\left[\frac{c(1-\rho^2)}{\sqrt{\pi}}\epsilon^{-c^2}\right]+\Phi\left(\frac{c}{\rho}\right)\times\left[\Phi\left(\frac{c}{\sqrt{1-\rho^2}}\right)-\left(\frac{1}{2}+c^2\right)\times\left(\frac{2c}{\sqrt{1-\rho^2}}\right)\right] \quad (36)$$

The total output power of a clipper is given by the substitution of unity for ρ in equation 36. The ratio of output power to input power is

$$\frac{\psi_{oo}(0)}{\sigma_i^2}=\frac{\sigma_o^2}{\sigma_i^2}=2c^2[1-\Phi(c)]+\Phi(c)-\frac{3c}{2\sqrt{\pi}}\epsilon^{-c^2} \quad (37)$$

Fig. 7 shows this output compared with the power which correlates with the input. A severely clipped signal is essentially a Poisson distribution of constant height

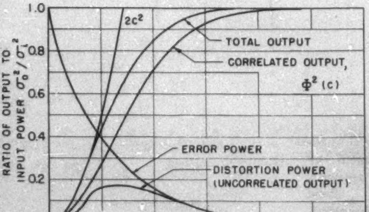

Fig. 7. Output powers of clipper with random Gaussian input. Total output is sum of correlated output and distortion power. At large inputs (small c), error is signal missing. At small inputs (large c), error is harmonic generation

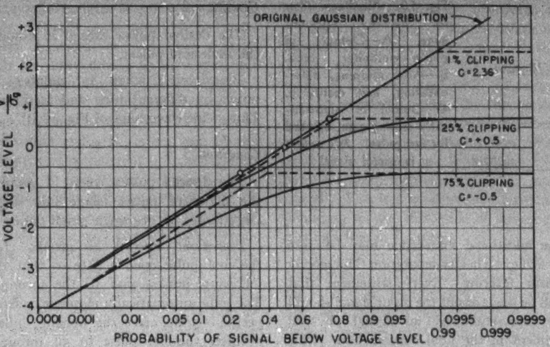

Fig. 8. Measured probability distribution of output of symmetrical clipper with random Gaussian input signal

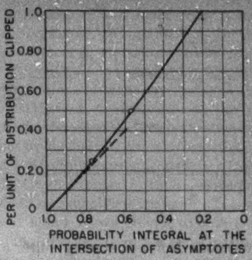

Fig. 9. Determination of spectrum of Gaussian signal prior to clipper from probability measurements after clipping. Curve is the termination of clipped distribution

and random crossings. This has a power of k^2 and a power gain of $2c^2$. The first term in equation 37 represents this severely clipped component.

A good approximation to the total output power is a Φ^2 curve with the abscissa shifted to the left.

$$\sigma_o^2=\psi_{oo}(0)\cong\sigma_i^2\Phi^2\left(c\sqrt{\frac{\pi}{2}}\right) \tag{38}$$

If clipping occurs on only one side, the output power is

$$\sigma_i^2\left[\frac{1}{2}+\frac{1}{2}\Phi^2\left(c\sqrt{\frac{\pi}{2}}\right)\right] \tag{39}$$

The distortion power, or uncorrelated output power, is the total output power in equation 39 for symmetrical clipping minus the correlated power, $\sigma^2\Phi^2(c)$, from equation 14.

$$\sigma_h^2=\psi_{hh}(0)=\sigma_i^2\left[(2c^2+\Phi(c))(1-\Phi(c))-\frac{3c}{2\sqrt{\pi}}\epsilon^{-c^2}\right]\cong\sigma_i^2\left[\Phi^2\left(\sqrt{\frac{\pi}{2}}c\right)-\Phi^2(c)\right] \tag{40}$$

This is, at most, about 18% of the input, but the power lost by the clipper is much greater. From the shapes of the curves, a good approximation for the distortion power in the output for symmetrical clipping is

$$\sigma_h^2\cong\sigma^2\frac{3c}{4\sqrt{\pi}}\epsilon^{-c^2} \tag{41}$$

Nearly all real components in actual systems have saturation levels, and one wishes to design for minimum cost or minimum weight, consistent with small distortion. There is no significant reduction in error power for increases in the clipping level above c of 2. This should be used to select components for high-accuracy proportional systems. If weight or cost increments are quite important, c should be small. A rule of thumb for typical electromechanical designs is a c of $\sqrt{2}$, or a clipping level of twice the rms input.

Non-Gaussian Input to Discontinuous-Slope Nonlinearity

A non-Gaussian input should be represented as being tailored by the same kind of unit as that which it supplies. For clippers or dead zone, one should approximate the input by a Gaussian signal passing through a combination of clippers and dead zone. Then, combine the signal operators with the actual equipment to obtain the over-all operator.

To measure the presence or absence of clipping, the actual probability distribution should be measured. This is done by constructing a clipper which passes all signals above a certain level, and a cumulative timer which runs whenever the signal exceeds the clipping level. The ratio of the timer reading to the actual time is the probability integral. Each point on the integral curve requires a separate run, or an additional clipper and timer.

Plot the measured data on probability integral paper as in Fig. 8. If the curve is a straight line, the distribution is Gaussian. If it is asymptotic to a voltage level, as in Fig. 8, the signal has been clipped on one side at that level. The clipped distribution lies to the right of the original distribution in Fig. 8 at all points. The horizontal value at any point is equal to the value on the original distribution, times the reciprocal of the per-unit clipping level. The slope at low probabilities matches the original distribution. The curved distribution may be moved back to the left until it becomes a terminated portion of the straight-line original distribution. The clipping level is the observed maximum level on the probability plot.

The per-unit clipping may be read directly in Fig. 9, after the asymptote is drawn, in Fig. 8, and the probability at the asymptote intersection read. One should locate the termination point of the original distribution at the clipping level, and a probability of one minus the per-unit clipping. The original distribution line is parallel to the sloping portion of the measured distribution. The original Gaussian rms value σ_y is available from the slope. It is the voltage between probabilities of 0.16 and 0.5. The original and final mean values are also available from the curves. The calculations may be checked, with the use of the previously derived equation 39.

Symmetrical clipping on both sides can be handled in exactly the same manner. The basic clipped curves are derived from the original straight line by applying the reciprocal of the clipping on each side as a correction factor to the deviation of the probability from 0.5 on that side.

This graphical method can also be used for the detection of tailoring by a dead zone, in which case a straight-line segment is removed from the middle of the Guassian distribution. The result of fitting the remaining segments together is that the ends of the curve bend to a greater slope, in the opposite direction from the clipped distribution.

Nonlinear Noise-Reducing Filter

One is able to use the criterion of minimum error power to design the best linear filter to separate information from noise, or to design the best linear predictor to compensate for an unalterable linear member. By changing the criterion to minimum error time, and the unalterable element to a nonlinear amplifier, one can obtain a nonlinear race-brake type of design.

In the previous sections, changes in a spectrum due to a nonlinearity have been obtained analytically, but whether these changes are improvements or not has not been considered.

Linear filters are used to separate information from noise when the only thing that is known is the power spectrum. If the amplitude distributions of the information and noise are different, or if the wave forms are different, or if anything else is known besides the power spectrum, the additional knowledge may be used to achieve a better separation than merely linear filtering. Every statement that can be made about the input signal should be represented by an actual physical element in the final construction. This will be illustrated by the following two examples.

A detector for very weak beta rays in the presence of extraneous strong beta radiation could use a scintillation crystal counter and a very long Lucite pipe to carry the light flashes to a photomultiplier tube. Thermal noise on the photocathode would produce individual small pulses. The undesired high-energy radiation in the scintillator would produce high-amplitude pulses. For each low-energy beta ray, light reflections in the long Lucite pipe would produce a train of small pulses, as shown in Fig. 10. Extraneous, undesired radiation and noise pulses can produce both large bursts of great energy and small individual pulses. A circuit can be built to discard most of the unwanted pulses, greatly improving the signal-to-noise ratio.

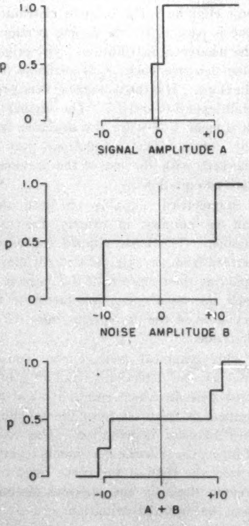

Fig. 11 (left). Amplitude probability integral distribution of signal and noise

Derivation of the Circuit

Condition 1

The number of desired signals is small; the number of undesired signals is large.

Procedure: Clip photomultiplier output at peak of desired signals. This removes most of the undesired energy.

Condition 2

The desired pulses exceed in number the undesired pulses.

Procedure: Change to number of pulses by differentiating and rectifying. This yields waveshape of Fig. 10(B).

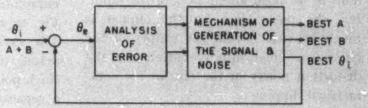
Condition 3

The desired pulses come in groups; the undesired pulses merge into single large pulses, or are single small pulses.

Procedure: Record only groups. Let the first pulse open a gate so that the following pulses pass to the recorder. The gate automatically closes in a short period of time, after the opening pulse, or after the last pulse to go through, so that no individual pulses reach the recorder.

The recorder receives signal shown in Fig. 10(C). This is a remarkable signal-to-noise improvement achieved entirely with nonlinear filtering. The power spectra of the desired and undesired signals were probably very similar. Only the amplitude probability distributions were different.

Another type of nonlinear filter is illustrated by Figs. 11 and 12. The input is a mixture of the two severely clipped Gaussian components in Fig. 11. The mechanism of the origin of the signal was a large amplitude Gaussian distribution which had been severely clipped at plus and minus one volt, so that it had 50% probability of each of these two values, and a negligible probability of any other value. The noise was also a Gaussian distribution which had been clipped at plus and minus 10 volts. The power spectra after clipping were identical, so that no separation of the signal from the noise was possible by linear means. The noise however, was 40 decibels greater than the signal. The signal can be completely separated from the noise by nonlinear means.



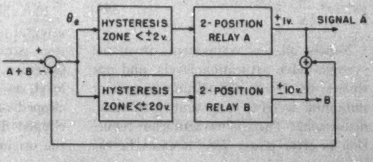


Fig. 12 (right). Nonlinear filter to separate signal and noise in Fig. 11. Filter makes a perfect separation of two components with identical power spectra

A nonlinear filter is similar to a linear filter in that it has a model of the mechanism of generation of the two signals, with the sum fed back to the input and forced to equal the input with a high-gain error amplifier. In addition, there is a block to analyze the error. The model mechanism in Fig. 12 is the sum of the outputs of two different polarized 2-position relays. The *A* relay delivers ±1 volt, and the *B* relay delivers ±10 volts.

If the error exceeds 2 volts, the *B* relay should change, and therefore its hysteresis band is made greater than ±2 volts. If the error is exactly 2 volts, the *A* relay should change and therefore its hysteresis band is less than ±2 volts. The *B* relay will first reproduce the noise input; then the *A* relay will reproduce the signal input. This nonlinear filter will always deliver a correct separation of the two input signals.

It is beyond the scope of this paper to consider nonlinear filters in general, but the method in Fig. 12 can be extended to separating signals with continuous smooth probability distributions. If the two signals each have finite values of probability density at the same amplitudes, then usually they cannot be separated completely without error.

Summary

A nondynamic nonlinearity delivers a power, a part of which is correlated with the input signal, and part of which is distortion, or harmonic power. For Gaussian inputs, the ratio of the CC to the input autocorrelation is the transference, or equivalent gain. The transference squared times the input power is the useful output power. The distortion power is not correlated with the input, but is correlated with the distortion power of other nonlinearities, wherever they may be in the system. For example, a clipper and a dead zone in parallel have distortion powers which may cancel. This is a good method for compensating for the distortion of undesired nonlinearities in a system.

The stability of a closed-loop system containing a nonlinearity is a function of the nonlinear transference. This nonlinear transference can be used with L-plane templates to determine the stability as a function of signal level. The power of the error between the output and the input can be used for specifying the minimum acceptable components for a system.

Non-Gaussian inputs should be represented by a Gaussian distribution tailored by the same kinds of nonlinearities as those which the actual system presents. Then the signal and the system components can be combined for analysis purposes.

A signal can be separated from undesirable noise with a linear dynamic filter if the signal and noise have different power spectra as a function of frequency. Signal and noise can be separated by nonlinear filters if they have the same power spectra but different probability distributions. The philosophy of separation is to build a model of the mechanism of generation of the signal from a flat Gaussian source, and another model of the mechanism of generation of the noise from a different flat Gaussian source. The sum of the outputs of these two models is the best statistical approximation to the input, and it is made identically equal to the input by subtracting the sum from the input and using the error to actuate a high-gain error amplifier. (In linear filters, infinite gain amplifiers are used. In nonlinear filters, relays provide infinite gain at the particular signal level which causes the relay to respond.) The output of the infinite gain error amplifier is examined to determine which error components are due to the signal and which to the noise. These components are separated with a nonlinear function, or with the relay hysteresis, and are used to generate the best guesses for the two flat Gaussian sources which supply the models.

Indialing to PBX Extensions: Application in a Step-by-Step Central Office Area

G. NORMAN SCHLEINKOFER
MEMBER AIEE

UP TO THE PRESENT TIME, the completion of an incoming call to a private branch exchange (PBX) extension telephone has been dependent upon a human attendant. She must determine what extension station is desired and do the proper switching of the call from the incoming trunk to the station. Indialing provides a means whereby the call is dialed directly from the general exchange system to the PBX station without the need for a human attendant, except for transfer and information services.

This paper will discuss the application of indialing in a step-by-step central office area. The headquarters PBX of E. I. du Pont de Nemours and Company (hereinafter referred to as the du Pont PBX) in Wilmington, Del., was chosen for a full-scale field trial. On more than 80% of the incoming calls to this PBX, the extension station was asked for by number. The Olympia central office, which serves this PBX, was readily adaptable for indialing. The customer had requested this type of service in connection with some additions and rearrangements that had become necessary.

Indialing is an extension of the mechanization program of the telephone system. This program began with the introduction of dial equipment, for local use only, early in the century and has progressed to a point where almost all stations are on a dial basis and a large part of these can dial points far beyond the local service area. Dialing of calls within

---

Paper 59-185, recommended by the AIEE Communications Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted October 10, 1958; made available for printing December 8, 1958.

G. NORMAN SCHLEINKOFER is with The Bell Telephone Company of Pennsylvania, Philadelphia, Pa.

a PBX and, to a limited extent, to the local area outside the PBX was introduced at about the same time.

Without indialing, the attendant requires additional time for each incoming call. This increases the average holding time of every call made to a PBX. The additional time consists of a few seconds for the trunk lamp to be illuminated, several seconds for the attendant to become conscious that a call is waiting and be free to answer it, quite a few more seconds to determine from the caller just what extension is desired, and finally a few seconds to make the connection and start ringing. The total is estimated to average about 30 seconds for the PBX under consideration.

The saving of this number of seconds may appear insignificant when only one call is considered. However, when applied to a large proportion of the calls to PBX's over the system, a considerable saving is made possible in the trunk plant, toll switching equipment, and operating effort of the telephone companies. The customer obtains better incoming service a reduction in the personnel for operating the switchboard, and a smaller monthly charge for the switchboard positions as well as other incidental and intangible advantages. As a by-product of the numbering system that must be used with indialing, it is possible for the customer to adopt better bill checking and accounting procedures.

To provide the advantages of indialing to everyone will require time and money. Time is involved because it is not possible to convert all PBX's for indialing without disrupting the orderly supply of material for growth, mechanization, and replacement of the remainder of the telephone system, because comparatively large amounts of equipment are required for each job. Money must be spent for the establishment of a new numbering scheme for the PBX, as well as for rearrangements of the trunk plant of the entire telephone system, the central office equipment, and the equipment at the PBX. Each of these expenses will be considered separately.

Fig. 1. Associated central office equipment, Wilmington, Del.

A—Before du Pont PBX indialing
B—After du Pont PBX indialing

Numbering Considerations

The first step toward indialing is to assign a 7-digit code consisting of two letters and five numerals to each PBX extension station. This 7-digit code must be compatible with the nation-wide numbering plan so that it may be reached from any telephone in the system. In the case of the du Pont PBX, an entire central office code with a possibility of 10,000 telephones was reserved. The code 774 was given the name PRospect 4. To this code was added the 4-digit extension number.

At the present time, the Delaware and eastern Pennsylvania areas are able to dial interchangeably on a 7-digit basis. This limits the assignment of a code to one that has not been pre-empted previously. Since Philadelphia has some panel-type central offices equipped with translator-senders, these limit the codes available to 200. A further limitation in the choice of codes was due to the arrangement of switches in the Olympia central office. Hence only those codes which could be assigned to established selector levels could be used. There was only one code available in the Olympia central office which had not been reserved for other purposes, so that it will not be possible to provide indialing services to other large customers until additional codes have been released from their present reservation.

The number of codes available will increase as the direct distance-dialing program progresses, the translator-senders of the Philadelphia central offices are replaced and it is necessary to install additional equipment in the Olympia central office for other purposes.

After the new code had been selected it was placed in the route information sheets of every central office operator in the entire telephone system, so that it could be reached from any point. New route cards were cut at all points arranged to switch direct distance-dialed calls automatically.

The listed call number to be used required careful consideration and was included in the series assigned to extension stations. If not selected carefully, it will reduce the codes remaining for assignment for other purposes. At the du Pont PBX the number chosen was PR 4-1000. Incoming calls were routed from the first level of the first selectors directly to the switchboard. This left the first level of the local first selectors free to be used for tie trunk, foreign exchange, and other service codes. The remaining levels may all be assigned to stations as required.

Trunking Changes

Since a new central office code was established to provide indialing, it was necessary to furnish this new central office with its complement of incoming trunks somewhat similar to the arrangement for the existing one. A study was made of the incoming traffic and its present routing. This study indicated the need for new groups of trunks from some of the near-by central offices, the augmentation of some of the present trunk groups, and the decrease of other trunk groups.

Since traffic from more distant points would arrive in Wilmington over the same paths as formerly, it was only necessary to establish paths from the toll switchboard and the toll train switches to the new code levels.

Trunking in the Olympia central office was most severely changed, since with indialing all of the traffic for this PBX will now pass through its own central office levels rather than through the Olympia train of switches. As can be seen by comparing Figs. 1(A) and 1(B), some of the equipment formerly used is no longer required and some must be installed just because of the new code.

There are three types of trunks feeding into the new PRospect 4 code:

1. Local trunks from the Olympia, Porter, Penns Grove, and Chester central offices.
2. Trunks from the toll switchboard and distant points, as well as Sycamore.
3. Trunks from points served by the local tandem network (East, Cadar, and Wyman central offices).

These trunks feed into separate groups of switches which accept a varying number of digits. The traffic from the switch groups is then combined and carried to the PBX through rotary out-trunk switches and outgoing repeaters which deliver the last four digits of the extension station number of the incoming selector.

Dial pulse-repeating circuits are used when trunking a call from one step-by-step central office to another and at times within the central office, especially when going from one type of circuit to another. If more than two repeaters are used in tandem, correcting circuits must be used to avoid pulse mutilation. Pulse-correcting circuits are expensive and are hard to maintain and therefore are not used unless another alternative is not available.

Some of the trunk routings were rearranged so that a maximum of only two pulse repeaters were in any one connection. It was also necessary to redesign the originally contemplated transfer circuit so as to eliminate a repeating feature.

Outgoing trunks from the PBX are used in the same manner as formerly. Foreign exchange and tie trunk points are reached by dialing available codes which have been derived from the first and other levels. Until the levels are needed for station purposes, local outgoing trunks are reached by dialing "9" and the attendant, by dialing "0." When these levels are required for station use, the services furnished by them will be transferred to some other available level, perhaps "19" and "10." This arrangement is the same as that usually provided for PBX's without indialing.

Local outgoing and incoming trunks are on a one-way basis, since no economy would result from combining the two groups.

Central Office Rearrangements

A circuit from a dial central office to an ordinary PBX is furnished from the same type of central office equipment that is used for a single telephone. The progress of the call is controlled by dial pulses until it leaves the central office when the signaling is changed to ringing current which actuates the equipment at the telephone or PBX. Because of the design of this equipment, dial pulses may not be passed from the central office to the PBX

However, by transferring some of the functions of the central office to the PBX, circuits can be installed so that dial pulses may be passed over them to operate switches and select a telephone at the PBX. In this way, the call leaves the central office on what otherwise might be considered an intra-office trunk.

Fig. 1(A) shows the arrangement of the central office equipment before indialing. At that time there were 76 PBX trunks from the Olympia step-by-step central office (OL 4-5121) to the 32-position manual switchboard at the PBX. These trunks are reached by means of level hunting connector switches which provided full access to groups of 100 trunks, in contrast to only 10 which may be reached through the usual type of step-by-step switch.

Local and toll calls used separate trains of switches and groups of level hunting connectors. Since the banks were multiplied, each switch has full access to all trunks.

Fig. 1(B) shows the arrangement of the central office equipment after indialing. The numerals under the switch symbols indicate the total number of switched of that type in the Olympia central office. By comparing the numbers as shown in Figs. 1(A) and 1(B), the differences in the equipment requirements may be seen.

The principal changes made in the central office were as follows:

1. An additional group of selector switches (Code "77") was installed.
2. Additional switches were placed in the Code "7" selector group of the toll train.
3. More switches were added to the local incoming selector group.
4. More switches were added to the Code "7" tandem selectors and the tandem incoming selectors.
5. New switchboard trunks from the toll switchboard and additional outgoing pulse repeating trunks from the Code "7" selectors of the toll train to the new Code "77" selectors were installed.
6. New rotary out-trunk switches and dial

pulse repeaters were provided between the central office selectors and the PBX.

7. The level hunting connectors of both the toll and local trains were eliminated.

8. The number of switches in the remaining groups of selectors of the local and toll trains except the local first selectors and incoming toll selectors were reduced.

Since the Olympia central office was equipped with digit-absorbing first selectors, a complete train of selectors to use each digit has not been installed. This type of switch obviated a costly equipment addition when this central office was changed from 5- to 7-digit dialing for local calls. However, the number of codes that can be reached is limited. All the available levels on the present selectors were in use so that a new bank of switches known as Code "77" selectors was installed to permit traffic from certain trunk groups to be routed to the new PR 4 central office code.

There were available in the Olympia central office outgoing repeaters similar to those in service for other purposes which were used to carry the circuits to the PBX. These were required to convert the circuits from 3-wire to 2-wire so as to avoid the use of extra cable pairs and sleeve repeaters.

Rotary out-trunk switches were provided on the trunks leading from the central office to the PBX for the following reasons:

1. To provide trunk efficiency equivalent to that available with level hunting connectors which were formerly in service.

2. It was found to be less costly to provide the rotary out-trunk switches than to install the extra equipment and cable plant for the additional trunks required if rotary out-trunk switches were not used.

3. The calling customer would have a considerably better chance of reaching the PBX without encountering a "false busy."

The local first selector and incoming toll selectors remain the same because substantially the same traffic feeds into them, although leaving via different levels. The differences in the quantities of other switches reflect the changed paths that the traffic must take to reach the new call number.

Most of the central office equipment which was released by the rerouting of the traffic could be readily reused for growth for other customers with the exception of the level hunting connectors.

B—After indialing

PBX Additions and Changes

Indialing requires that some of the functions of the central office be preformed at the PBX. The two letters and one numeral of the central office code of each extension station are used in the central office for directing the call to the customer's location and only the last four digits are delivered to the first switch in the PBX which directs the call to the extension station. This is compatible with the present method which uses four digits to dial from one station to another within the PBX.

The new equipment required at the PBX consisted of the incoming selectors, the transfer circuits, the trunk circuits for the listed number trunks, an intercepting arrangement, and switchboard jack appearances for these circuits. The traffic from the incoming selectors is routed over common trains of second selectors and connectors with all other types of calls. The switches in these trains were increased to handle the added traffic. This resulted in a considerable saving in equipment over that required if separate trains had been used.

The tariff which applies to PBX equipment in Delaware permits the telephone company to install the number of switches required for a standard grade of service. In most other states the customer pays for the number of switches installed and can choose any grade of service he desires. It is important that all switches associated with indialing be under the control of the telephone company; otherwise, the action of the customer could have a serious effect on telephone service in general.

When indialing was first suggested for the du Pont PBX, it was equipped for 4,900 lines and 32 positions of the latest type of switchboard, having a 7-panel station multiple. However, the use of four of these positions had been suspended. Because of indialing, six additional positions were disconnected. Although the use of a total of ten positions was discontinued, only six were removed, leaving the other four for expected growth in other traffic.

The reduction in the number of positions due to indialing is difficult to evaluate. Many of the positions are used exclusively for tie trunk and foreign exchange traffic, and the number used for answering incoming calls varies with the need. All positions are not staffed continuously but are programed to follow the load. In this way, a particular position may be used for different purposes at different times. Although it is expected that 90% of the incoming calls will be in-dialed, this does not mean that the incoming load will be reduced by 90%. The remaining 10% of the calls are expected to be those that require the most effort on the part of the attendant. In addition, the attendant must still perform any transfer and information services required.

Because more than average space was occupied by the trunk multiple, additional station jacks would have been beyond the reasonable reach of the attendant. It was necessary, therefore, to resort to some other method of completing calls from the switchboard to the telephone at the extension station. Attendant dialing of all these calls was the alternative used and required the replacement of all the station multiple with switching equipment.

At the same time that indialing was installed, 300 additional station lines were added for growth, bringing the total to 5,200. This required using the seventh level for station assignment. The seventh level was formerly used for tie trunk codes. Other codes derived from the first level of the first selectors were used for this purpose, involving a rearrangement of the trunking.

Although 76 incoming trunks had been in service before indialing, the load on them had grown to a point that more than standard delays were encountered during the busy hour. To bring the delay factor back to standard and to care for the additional business generated by the 300 new stations required that 97 trunks be placed in service. Each of these trunks has a jack appearance on the switchboard to permit the transfer of calls.

A separate complement of jacks was provided in the switchboard to answer listed number calls (PR 4-1000). However, since these calls were routed through the selector banks it was necessary to provide only enough jacks to carry the traffic rather than install one for each trunk.

To be able to charge properly for the indialed calls and not charge for those that reached an unused terminal, a recorded message type of intercepting service was installed. It was not feasible to have the attendant give this information, since a call could be dialed to a known unused terminal and, when the attendant answered, a message that should be paid for could be given to her without being charged to the calling telephone. Calls from outside the PBX, as well as those dialed within it reach the same unused terminals. This made it necessary to develop wording which would give understandable information to both types of calls in one message.

Fig. 2(A) shows the switching equipment at the PBX before indialing and Fig. 2(B) shows it afterward.

Attendant Dialing

Attendant dialing at this PBX was a a necessity because of space limitations in the face of the switchboard. However, the introduction of attendant dialing should be considered at the same time as indialing. It is not economical to provide attendant dialing prior to indialing because large amount of switchboard equipment needed to handle the calls that will be indialed subsequently. If attendant dialing is provided after indialing, some false work work may be done in installing additional multiple, which may have to be removed later. For large PBX's with indialing the attendant dialing equipment is considerably less expensive than multiple, especially when common trains of switches are used.

In choosing between 2-, 3-, or 4-digit attendant dialing, four digits were adopted. This resulted in a smaller number of items of equipment and a better arrangement of jacks. Two- or 3 digit dialing would require a varying number of jacks in a large number of groups, which could not be satisfactorily fitted into the 20-jacks-per-strip arrangement of the switchboard.

The removal of the station multiple made available much needed space into which the trunk multiple was expanded. This expandion was due not only to the jacks needed for attendant dialing trunks that replaced the station multiple but also for increased requirements in the number of central office trunks, tie trunks, attendant trunks, and other services that have jack appearances.

Transfer Circuit

In order to give full PBX service required at the headquarters of the du Pont Company, it was necessary to provide for the transfer of calls from one extension station to another. Since this service is not used in central offices, nor in PBX's up to the present time, the local customer services engineers were obliged to develop a suitable transfer circuit.

This circuit must perform the following functions:

1. Pass the incoming call to the selectors with a minimum of interference with the dial pulses.
2. Notify the central office equipment when the called station answers, and also when it disconnects.
3. Recognize the difference between flashing for a transfer and a permanent disconnection.
4. Cause a lamp to light on the switchboard when a transfer request is received.
5. Prevent any transfer request from reaching the preceding equipment so as to avoid a premature disconnection.
6. Provide a 3-way connection between the calling and called parties and the PBX attendant.
7. Release the local switching equipment between the transfer circuit and the called telephone after the transfer information has been given to the PBX attendant and the original called party has hung up.
8. Establish a new talking path between the incoming circuit and the switchboard.
9. Allow any number of subsequent transers under the control of the switchboard cords.
10. Hold the trunk busy until the calling party disconnects, but permit the release of the local switches if the called party disconnects first.

11. Restore to normal when the distant called party disconnects.

12. Deny access to the trunk by the attendant before the first transfer request is made to maintain secrecy and to avoid interference with the initial progress of the call.

All of these functions were combined in a relay unit which was manufactured by the Western Electric Company and installed in each indialing trunk circuit.

The transfer circuit was arranged so that it passed dial pulses directly into the indialing selectors. When the called party answered, a repeating coil was inserted in the circuit to separate the central office and PBX circuits. This separation permitted a delay in passing supervision to the calling central office. This delay was necessary to prevent a transfer flash from appearing as a disconnect signal.

Conclusions

The indialing equipment was officially placed in service at the opening of business on July 7, 1958. There was no "cutover" as such, because practically all the circuits had been cut through for almost a week previously and had been used for test calls and by others who had the necessary information.

The existing trunks from the Olympia call number were not immediately disconnected but were left in service to avoid an excessive intercepting load at the central office and to reduce the necessity of having the calling customer place two calls if he either was not informed of the change in number or neglected to use it. Any caller who used the old number was informed of the new one by the PBX attendant before completing the call so that he would know the proper dialing procedure for subsequent calls.

Almost immediately, indialed calls amounted to over 80% of the total and soon built up to about 90%.

Indialing, together with attendant dialing and the transfer feature, operated to the entire satisfaction of this customer. However, this is not to be taken as an indication that indialing would be satisfactory for every PBX. Different problems of transmission, supervision, numbering, dialing, load characteristics, and trunking must be solved in each case.

Basic Concepts of Multidimensional Space Filters

GABRIEL KRON
FELLOW AIEE

Synopsis: The conventional electric network, consisting of linear or one-dimensional *RLC* (resistance-inductance-capacitance) elements, may be generalized by adding to it planar-, cubic-, etc., up to k-dimensional *RLC* elements. The resultant geometrical configuration of 0-, 1-, 2-. . . to k-dimensional spatial networks interconnected into one structure is called, in combinatorial topology, a "polyhedron." Its electric-network realization may be called a "wave model." The electromagnetic structure formed by interconnecting two or more wave models into one network, will be called a "multidimensional space filter." The latter is expected to be employed eventually for the theoretical and perhaps practical solution of such physical problems for which the conventional linear (one-dimensional) electric filter is used today, on a much more elaborate multidimensional scale, of course. A single polyhedron is expected to be used in the numerical solution of simpler multidimensional problems of the calculus of finite differences, having nonuniform space intervals.

This paper illustrates the establishment of the basic tensors of a space filter by means of a tetrahedron. In particular, it is shown that if the space filter is torn apart structurally into a set of isolated polyhedra, and if each polyhedron is torn apart dimensionally into a set of isolated q-networks (each with q-dimensional elements), the theories and equations of a linear 1-network are applicable to each q-network separately. It is, however, necessary that the equivalent linear network should be considered as an "orthogonal" network having nonsingular (square) connection tensors C and A. Each q-network also has a complete set of junction-pair and mesh equations properly coupled (the complete set of equations is needed when the isolated q-networks are interconnected). The incidence matrices arising after interconnection are also given. The steps for propagating an electromagnetic wave through an isolated q-network are shown and the wave vectors are considered to define geometrically a qth order "divided difference." Simplified algebraic diagrams are also developed. During the solution process these diagrams are to be used in place of q-dimensional graphs.

The process of interconnecting the component q networks into a wave model and several of the latter into a space filter, utilizes the entire apparatus of the method of tearing.[1] A series connection is shown in the paper.

Two Storehouses of Information

In trying to analyze and solve extremely complicated physical, economic, or other systems with a very large number of variables, the author is gradually evolving a new philosophy of attack. Throughout the analysis and solution of the system he utilizes simultaneously two storehouses of information: 1. the mathematical equations of the system, and 2. a topological model of the system, or the system itself.

The model (or the system) is assumed to consist of two component parts: 1. an underlying "dead" topological structure, which represents the independent variables and structural parameters in the form of multiply connected spaces, and 2. a superimposed "live" algebraic structure, which represents the dependent variables and nonstructural parameters in the form of electromagnetic and other physical vectors propagating across the various spaces and between the various polyhedra.

Both geometry and physics associated with the model are continuously put to use to direct the mathematical unfolding of the solution process. At every intermediate step there exists a 3-pronged alteration upon, and a three fold exchange of information between the mathematics, geometry, and physics of the system. The triangular manipulation and flow of information continues in unison until the final solution of the problem has been reached.

THE ORTHOGONAL POINT OF VIEW

To apply linear networks for the piece-by-piece analysis and solution of large-scale nonelectrical problems, a comprehensive orthogonal point of view was developed.[1,2] The unified theory represents a combination of the mesh and junction-pair points of view. The over-

---

Paper 59-228, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1-6, 1959. Manuscript submitted October 27, 1958; made available for printing December 3, 1958.

GABRIEL KRON is with the General Electric Company, Schenectady, N. Y.

all view brought to light the simultaneous existence of four types of currents and four types of voltages in the same linear network.

Contrary to recent trends, the author has consistently refused to drag in the concepts of junction points (0-space) and planes (2-space) as constituent or auxiliary parts of a linear network. By stopping at the upper and lower boundaries (at the meshes and junction pairs), and not extending beyond them, a self-consistent topological structure and algebraic diagram could be constructed for a linear network. As a result, all linear concepts remain valid, first of all for a single higher-dimensional network. Moreover, the existence of self-consistent building blocks makes it possible to interconnect a whole sequence of multidimensional networks into one logical structure, a polyhedron (or wave model), with the same facility, as several subdivisions of a linear network are interconnected into one structure. The interconnection of wave models into a space filter follows the steps for constructing supernetworks out of already solved networks.

ANTICIPATED FIELDS OF APPLICATION

Generally speaking, the use of a polyhedron appears to the author as a novel method for solving a class of problems in which the large number of independent variables and parameters are nonlinear. (The dependent variables are still linear as long as the volume elements of the polyhedron are Euclidean spaces. Of course, the volume elements may be assumed to be non-Euclidean.) The most obvious and simplest application of a polyhedron, or rather, a wave model, is to generalize the various formulas of the calculus of finite differences for nonuniform intervals assumed in a k-dimensional Euclidean space. This paper restricts itself to generalizing the concept of divided differences of various orders. They are expected to be used for interpolation, curve fitting, smoothing, numerical differentiation, and integration, and for other problems with which the calculus of finite differences deals.

Partial differential equations, integral equations, and integropartial differential equations require too many net points in more than two or three dimensions, if the net points are regularly spaced. However, a comparatively few points spaced at random can adequately represent very large dimensional spaces. Thus it is hoped that the space-filter approach will eventually open up new avenues for solving systematically advanced types of physical problems described by simultaneous equations with a very large number of independent variables and parameters. The space filter is expected to consider during the solution process not only the unknown function, but also all its higher derivatives near the given points, all simultaneously, as the several polyhedra will be properly staggered within the confines of the enveloping k space.

It is anticipated that advanced problems in numerical analysis (Fourier transform, power density spectra), in operations research (quadratic and higher programing), in economics, etc., will also offer opportunities for the use of space filters. The study of diffraction and scattering of electromagnetic waves in asymmetrical crystal and molecular structures would only be a first step into an ever-widening field of physical application for multidimensional space-filter concepts.

THE PROCESS OF TEARING

In solving problems of linear networks[1] the networks were usually torn into subdivisions only when the number of cuts was far less than the number of original variables. In that case, the intersection matrix z_4 to be inverted had far fewer rows and columns than the inverted matrix Z of the original network. The polyhedron offers an example where the intersection network, constructed by tearing the system apart dimensionwise, has practically as many rows and columns as the original network. However, the factorized form of the inverse is now triple-diagonal, while the true inverse of the original network is a full matrix.

Moreover, the hidden variables liberated at the cuts represent now the main informations sought, such as the regression coefficients (in curve fitting), or the displacements of atoms (in diffraction studies). In linear networks the hidden variables are needed for auxiliary use only and are not of primary interest.

The analysis and solution of wave models and space filters in a piecewise manner appears to be unavoidable from either an organizational or a computational point of view. Since the process of tearing and its accompanying topological concepts are unknown to both engineers and physicists, this fact alone may explain the reason for the complete absence of polyhedra and space filters in the solution of physical or numerical problems. The occasional use of polyhedra in the design of experiments, or in molecular packing, etc., has no relation to the present study since the polyhedra are not energized. This paper endows the polyhedron with a superimposed electromagnetic wave; that is, here a "dead" polyhedron is turned into a "live" one.

SIX BASIC STEPS IN A "PRIMITIVE" POLYHEDRON

No matter for what analytical problem the space filter is employed, the first step in its application is to tear the space filter apart structurewise into isolated polyhedra, then tear each polyhedron apart dimensionwise into isolated q-networks and perform as many operations on the isolated q-networks as possible. This paper deals with six of the basic operations that are to be performed on each q-network (the "primitive" polyhedron) in any problem. All these manipulations are repetition, or straightforward generalization, of those performed on a torn but conventional linear network. The six basic steps are:

1. A sequence of 0-, 1-, 2-, to k-dimensional networks is constructed between n vertices defined by the independent variables.

2. Each q-network is torn apart further into its constituent volume elements, the primitive q-network.

3. A diagonal $Z_{\alpha\beta}{}^{(q)}$ or $Y_{(q)}{}^{\alpha\beta}$ matrix, the "metric tensor," is set up for each q-network, representing the square of the q-dimensional volume of the component elements. (A full matrix may be set up if so desired, containing also all the direction cosines.)

4. Each q-network is interconnected separately by establishing a nonsingular square "connection tensor" $C_{\alpha'}{}^{\alpha(q)}$. Its inverse $A^q = C_t^{q-1}$ is also calculated.

5. Each nonsingular connection matrix C and its inverse A is partitioned into two rectangular matrices, the "boundary operators" C_m, C_j, and A^m, A^j. (Out of the latter a set of rectangular "incidence matrices," M, and reciprocal incidence matrices M^{-1} may be set up. These rectangular matrices show the relations between two neighboring q-networks, and serve as a check on the correctness of the boundary operators.)

6. By assuming the dependent variables $y_\alpha{}^{(p)}$ (one or p sets) as bound magnetic poles $\dot{p}_{m0}{}^{(b)} = \dot{B}_0$ (alternating at say 60 cycles) placed on the vertices of the 0-network, an electromagnetic wave is allowed to spread across the open-circuited space filter. The transversal waves with $\dot{e}_\alpha$, $\dot{b}_m$, h^α, and $\dot{d}_\alpha$ vectors, as well as the longitudinal waves with E_m, $\dot{B}_\alpha$, H^α, and $\dot{D}_\alpha$ (or $\dot{p}_m{}^{(f)}$, $\dot{p}_m{}^{(b)}$, $\dot{\rho}_{(f)}{}^{e}$, $\dot{\rho}_{(b)}{}^{e}$) vectors, appearing on each q-network, represent generalized divided differences of qth order, or rather, their covariant and contravariant forms. No back-reaction exists during this open-circuited propagation.

As the manipulation of each q-network involves further succession of pointwise or functional tearings, the practical solution of any space-filter problem involves thus a hierarchy of "tearing within tearing." The author is confident that the basic theory of such multiple tearings

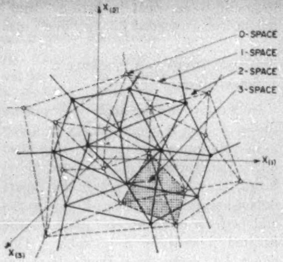

Fig. 1. Three-dimensional space filter formed by two polyhedra

has been satisfactorily covered in his publications of diakoptics.[1,2]

The connection matrix C^q of each q-network consists of +1, −1, and 0 elements. Their inverse calculation is rather simple and can be performed by longhand. Also all impedance matrices $Z_{\alpha\beta}{}^{(q)}$ and $Y_{(q)}{}^{\alpha\beta}$ belong to the isolated networks only and are diagonal. That is, the establishment of the sequence of divided differences will involve only the products of matrices with vectors (for one dependent variable).

Expressed in another manner, in simple problems the polyhedron is left open-circuited. The wave propagation is directed by the engineer and not by the structure itself. In more advanced studies the entire gamut of conventional wave propagations will appear in generalized forms. The networks will be connected into a polyhedron.

Constructing the Sequence of Networks

TEARING INTO ISOLATED NETWORKS

In order to establish the basic equations of state of a system of k multidimensional networks, the same steps will be followed as are used by the author in the analysis of other complex systems:

1. Tear the complex into isolated q-networks. Each network includes its own upper and lower boundaries, but not those of its neighbors.
2. Set up the equations of state of each q-network separately, as if the other q-networks were nonexistent.
3. Interconnect the q-networks and their equations of state with the aid of a connection tensor C representing their topological interrelations.

Fortunately each two neighboring q-networks have the same number of upper or lower boundaries. They are also similarly situated in space. Hence their interconnection into one system will be simple and painless. The connection matrix C consists of two equal unit matrices once the boundary axes have been matched.

0-DIMENSIONAL (POINT) NETWORK

To each value of the dependent variable y_α (with n components) belongs one value of each of the k independent variables $x_{(k)}{}^\alpha$. These k values of $x_{(k)}{}^\alpha$ are assumed as one point in a k-dimensional Euclidean space. Altogether there are n such points or vertices. The free index α is assumed to vary from one to n.

These n vertices define the 0-dimensional network. Its lower boundaries are the subnetworks (one, in the present case). Its upper boundaries are formed by the junction pairs (their number is $n-1$).

ONE-DIMENSIONAL (LINEAR) NETWORK

The next step is to erect, between the n points, a linear structure that covers the k-dimensional space with a network of one-dimensional lines or reference axes. Since these axes cannot be the conventional orthogonal straight lines, the aim is to approximate the latter as closely as possible (Fig. 1).

If all distances between sets of two points have been calculated, then: 1. the points inside the k-space are connected with about $2k$ points that are nearest; 2. the points at corners of the k-space are connected to only about k neighboring points; and 3. the points along the edges have $k+1$ neighbors, and so on.

The square of the length of each branch will be called "dielectric reluctance" $\epsilon_{\alpha\beta}{}^1$ (or impedance $Z_{\alpha\beta}{}^1$). The linear network is a dielectric network, at least in the interpolation problem.

q-DIMENSIONAL NETWORKS

The next step is to connect neighboring branches with planes (Fig. 1). Each plane will lie between three (or more) vertices. The aim is again to approximate a set of orthogonal planes connecting neighboring lines. The square of a triangular area will be called "magnetic reluctance" $\mu_{\alpha\beta}{}^2$ (or impedance $Z_{\alpha\beta}{}^2$). The planar network is a magnetic network.

Next, the neighboring triangles are connected with tetrahedrons, defined by four (or more) points, to form a 3-dimensional (cubic) reference network (Fig. 1). Then a set of five points defines a 4-dimensional network and in general a set of $q+1$ vertices defines a q-dimensional network.

The square of a q-dimensional volume element defines an impedance $Z^{(q)}$ (i.e. $\epsilon_{\alpha\beta}{}^{(q)}$ or $\mu_{\alpha\beta}{}^{(q)}$). For each primitive network the impedances are arranged along the diagonal of a matrix $Z_{\alpha\beta}{}^{(q)}$. Its inverse is $Y_{(q)}{}^{\alpha\beta}$ (i.e., $\epsilon_{(q)}{}^{\alpha\beta}$ or $\mu_{(q)}{}^{\alpha\beta}$). In general, the even-dimensional networks are magnetic, the odd-dimensional networks are dielectric.

q-DIMENSIONAL JUNCTION PAIRS AND MESHES

Each q-network will be organized in the same manner as a linear network has

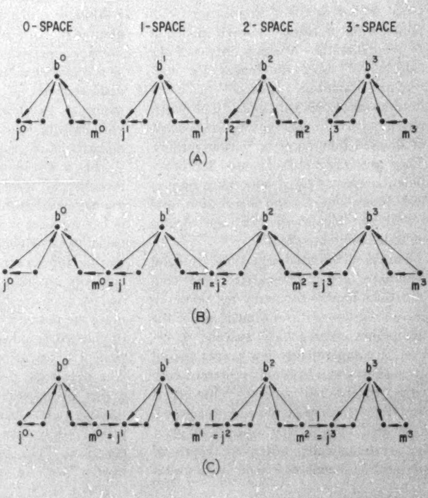

Fig. 2. Sequence of q spaces and their boundary spaces

A—Before interconnection
B—After interconnection
C—Separating joint boundary spaces by unit arrows

been organized. The steps will follow those developed in references 1 and 2.

With a linear 1-network having $b^{(1)}$ branches, two types of boundary concepts are associated. One of the concepts implies elements of a 0-network, the other concept suggests those of a 2-network. These two types of concepts (so-called "cycles") are

1. $j^{(1)}$ junction pairs. Each branch (or several branches) is bounded by two vertices (elements of a 0-network). The vertices do not belong to the 1-network.

2. $m^{(1)}$ meshes. A mesh forms the boundary of a plane (element of a 2-network). The planes do not belong to the 1-network.

The relation between the independent number of cycles (Betti numbers) and the number of branches is

$$b^{(1)}=j^{(1)}+m^{(1)} \tag{1}$$

Boundaries and Coboundaries

With a q network having $b^{(q)}$ component volume elements (branches), two types of boundary concepts (cycles) are associated, one implying $q-1$, the other $q+1$-dimensional volume elements. These two types of cycles are

1. $j^{(q)}$ junction pairs or boundaries. Each q volume of the q network is bounded by a $q-1$-dimensional surface. The latter is not part of the q-network.

2. $m^{(q)}$ meshes or coboundaries. A mesh (several q-surfaces) forms the boundary of a $(q+1)$ volume. The latter is again not part of the q-network.

The relation between the independent number of cycles (Betti numbers) and q-volumes is

$$b^{(q)}=j^{(q)}+m^{(q)} \tag{2A}$$

Interconnection of q-Networks

Each q-network (and its two types of boundaries) is established independently of the others. When the boundaries are interconnected into a sequence of networks, the upper boundary (m) of a $q-1$ space unites with the lower boundary (j) of a q-space to form one boundary. That is, the number of neighboring boundary and coboundary elements is the same

$$m^{(q-1)}=j^{(q)} \tag{2B}$$

Thus one portion of the connection matrix consists of two equal unit matrices with $j^{(q)}$ diagonal unities

$$A_q^{q-1}=C_q^{q-1}=\begin{array}{c|c} & c_q^{q-1} \\ m^{q-1} & 1 \\ j^q & 1 \end{array} \tag{2C}$$

Each q-network may be connected to its upper or lower neighbor either in shunt, or in series, or in some other manner. (Similarly the several polyhedra may be connected to each other in a large variety of ways and may also be inductively coupled to each other.) The manner of interconnection depends on the problem at hand and the nature of known and unknown quantities. The entire apparatus of diakoptics[1] with its mesh or junction intersection network concepts is needed to interconnect the isolated q-networks into a polyhedron and to interconnect the isolated polyhedra into various types of space filters.

Orthogonal Networks

Orthogonal Linear Networks

In order to understand the necessity for the construction of square, or rather, nonsingular, connection matrices C^q, it is necessary to sidestep and review the self-consistent orthogonal point of view of a linear network. The theory is also self-sufficient, as it must and does explain all characteristics of a linear network without dragging in extraneous features, such as junction points or planes.

Conventional theories analyze a linear electric circuit (after Maxwell) in two different ways:

1. As a mesh network, containing $m^{(1)}$ meshes only and described by a set of $m^{(1)}$ equations:

$$e_m=z_{mm}i^m \tag{3A}$$

2. As a junction network, containing $j^{(1)}$ junction pairs only, and described by a set of $j^{(1)}$ equations:

$$I^j=Y^{jj}E_j \tag{3B}$$

(Maxwell used a single datum point and not arbitrary junction pairs.)

In order to use electric-circuit theories for the analysis and solution of nonelectrical problems (or for more advanced electrical problems) the author has developed, in references 1 and 2, a more general orthogonal theory that includes the mesh and junction-pair theories as special cases. A linear network is assumed to possess simultaneously both meshes and junction pairs, and thus it is possible to write, for any linear network, as many equations as there are branches, $b^{(1)}$.

$$\begin{array}{l|l} e_m=z_{mm}i^m+z_{mj}I^j & I^j=Y^{jj}E_j+Y_{jm}e_m \\ E_j=z_{jm}i^m+z_{jj}I^j & i^m=Y^{mj}E_j+Y^{mm}e_m \end{array} \tag{3C}$$

That is, each network possesses simultaneously two types of currents and voltages:

1. Solenoidal (mesh) vectors i^m, e_m (denoted by lower-case letters).

2. Lamellar (jp) vectors I^m, E_m (denoted by capital letters).

More general quantities and equations have also been introduced[1,2] but they are not needed for the immediate problem.

Orthogonal q-Networks

The same orthogonal point of view will now be applied to each multidimensional q-network separately, with some modification. The main change is that the networks will conduct not electric currents, but electromagnetic waves (and charges). In particular: 1. all odd-dimensional spaces (1, 3, 5. . .) conduct two types of dielectric quantities: (a). solenoidal $\dot{d}^\alpha$, e_α, and (b). lamellar $\dot{D}^\alpha$, E^α; and 2. all even-dimensional spaces (0, 2, 4. . .) conduct two types of magnetic quantities: (a). solenoidal h^α, b_α, and (b). lamellar H^α, $\dot{B}_\alpha$.

Accordingly the impedance matrices will be denoted by $\epsilon_{\alpha\beta}$, $\epsilon^{\alpha\beta}$ and $\mu_{\alpha\beta}$, $\mu^{\alpha\beta}$ respectively, but often the $Z_{\alpha\beta}$ and $Y^{\alpha\beta}$ notation will also be used.

Note: The author suggests that in routine calculations it is sufficient to use only linear network terminology and notation e, I, z, and Y for the entire system. The number of dimensions may be denoted by an index.

The physically correct notation and terminology must be retained, however, to present the new concepts in their proper setting.

Topological Representation of Charges

To the author at least, it is a very remarkable fact that all lamellar (capital letter) quantities have to be identified with electric charges ρ^e and magnetic poles ρ_m, in order to satisfy Maxwell's equations. In particular, let: 1. $\rho_{(b)}$ represent "bound" charges, and 2. $\rho_{(f)}$ represent "free" charges.

In that case the following identification can be made:

$$\begin{array}{l|l} \dot{D}^\alpha\equiv\dot{\rho}_{(b)}{}^e & H^\alpha\equiv\dot{\rho}_{(f)}{}^e \\ E_\alpha\equiv\dot{\rho}_m{}^{(f)} & \dot{B}_\alpha\equiv\dot{\rho}_m{}^{(b)} \end{array} \tag{4A}$$

In considering the incidence matrices M as differential operators, this identifi-

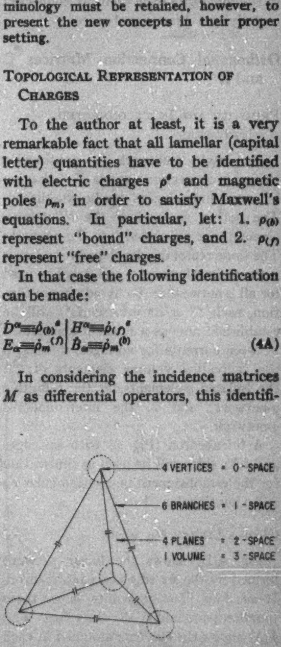

Fig. 3. Tetrahedron

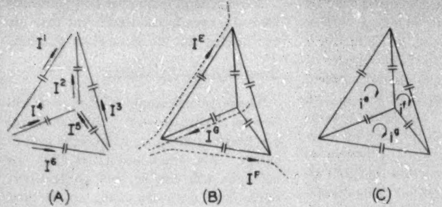

Fig. 4. Linear networks

A—Primitive 1-network
B—Junction pairs
C—Meshes

cation satisfies Maxwell's equation in all dimensions.

$$\text{div}(\dot{D}^{\alpha}+\dot{d}^{\alpha})=H^{\alpha}=\dot{\rho}_{(f)}^{e}$$
$$\text{div}(\dot{B}^{\alpha}+\dot{b}^{\alpha})=E_{\alpha}=\dot{\rho}_{m}^{(f)} \qquad (4B)$$

This identification (in multiply-connected spaces) of lamellar flux lines with point charges is in line with the modern trend to explain the physical existence of charges and particles by assuming the underlying 4-dimensional physical space as multiply connected.[3] In that case the charges and particles are no longer assumed to be singularities in a simply connected space, but are flux lines trapped in the topology of the multiply connected underlying 4-dimensional space.

Orthogonal Connection Matrices C and A

Primitive and Interconnected q-Networks

For each q-network a nonsingular (square) connection matrix $C_{\alpha}{}^{\alpha}$, having $b^{(q)}$ rows and columns, can be established. The matrix shows how the $b^{(q)}$ volume elements are connected into a q-network. The same reasoning developed for a linear network in references 1 and 3 will be used for all q-networks. To avoid circumlocution, each C^q(or its inverse $A_t{}^q$) will be established now as a relation maintained between currents (or voltages) flowing in the individual volume elements of: 1. the isolated q-elements, or the primitive q-network, and 2. the interconnected q-network.

A tetrahedron (Fig. 3) with six edges and four sides will be used as illustration for the establishment of a nonsingular C^1 and a nonsingular C^2.

C^1 of a Linear Network

Fig. 4(B) shows the linear network formed by the six edges of a tetrahedron. It has four junction points, hence three junction pairs and 6−3=3 meshes. Fig. 4(A) shows the currents assumed in each isolated branch. Equating the currents flowing in each branch before and after interconnection, the following relation exists:

$$I^1=C^1(I^{1'}+i^{1'}) \qquad (5A)$$

$$\begin{array}{c} \\ 1\\2\\3\\4\\5\\6 \end{array}\begin{array}{c} \\ \begin{bmatrix} I^1\\I^2\\I^3\\I^4\\I^5\\I^6 \end{bmatrix} \end{array} \begin{array}{c} \\ = \end{array} \begin{array}{c} \begin{array}{ccc|ccc} I^E & I^F & I^G & i^e & i^f & i^g \end{array} \\ \left[\begin{array}{ccc|ccc} 1 & & & 1 & & \\ & & & -1 & 1 & \\ & & & & -1 & \\ & & -1 & -1 & & 1 \\ & & & & 1 & -1 \\ & 1 & & & & -1 \end{array}\right] \end{array}$$

$$\begin{array}{c} [I^{1'} \quad i^{1'}] \\ =[C_j{}^1 \quad C_m{}^1] \end{array} \qquad (5B)$$

A vertical partition splits the square C^1 into two rectangular matrices. The mesh method of Maxwell utilizes $C_m{}^1$ only.

The inverse of C^{-1} is

$$A_{1t}=\begin{array}{c|cccccc|} & 1 & 2 & 3 & 4 & 5 & 6 \\ E & 1 & 1 & 1 & & & \\ F & & & -1 & & -1 & 1 \\ G & & 1 & & -1 & -1 & \\ \hline e & & -1 & -1 & & & \\ f & & & -1 & & & \\ g & & & -1 & & -1 & \end{array}=\begin{bmatrix} A_{1t}{}^j \\ A_{1t}{}^m \end{bmatrix} \qquad (5C)$$

A horizontal line partitions the square into two rectangular matrices. Only $A_{1t}{}^j$ is utilized by the junction method of Maxwell.

C^2 of a Planar Network

Fig. 5(A) shows the four planes of the tetrahedron. Fig. 5(B) shows the three independent meshes that bound three of the planes, and Fig. 5(C) shows the single closed surface formed by four planes. Thus 4=3+1. The closed surface is represented by one current I^s only.

Equating the currents flowing in each plane before and after interconnection, the following nonsingular relation exists:

$$I^2=C^2(i^{2'}+I^{2'}) \qquad (6A)$$

$$\begin{bmatrix} I^a\\I^b\\I^c\\I^d \end{bmatrix} = \begin{array}{c} \begin{array}{ccc|c} i^e & i^f & i^g & I^s \end{array} \\ \left[\begin{array}{ccc|c} 1 & & & 1 \\ & 1 & & 1 \\ & & 1 & 1 \\ & & & -1 \end{array}\right] \end{array} = \begin{array}{c} [i^{2'} \quad I^{2'}] \\ {[C_j{}^2 \quad C_m{}^2]} \end{array} \qquad (6B)$$

Now the previous meshes play the role of junction pairs (boundaries) and the closed surface plays the role of meshes (coboundaries).

The inverse of C^2 is

$$A_{2t}=\begin{array}{c|cccc|} & a & b & c & d \\ e & 1 & & & 1 \\ f & & 1 & & 1 \\ g & & & 1 & 1 \\ \hline s & & & & -1 \end{array}=\begin{bmatrix} A_{2t}{}^j \\ A_{2t}{}^m \end{bmatrix} \qquad (6C)$$

Incidence Matrices M and M^{-1}

Algebraic Diagram of a Linear Network

It has been shown in reference 1 that, in a linear network, the two square connection matrices C and A, as well as their four partitioned matrices (boundary operators) can be arranged into an algebraic diagram (vector diagram) shown in Fig. 6(A). Each arrow represents a matrix and the sum of two arrows represents the product of two matrices. (In taking sums, the directions go against the arrows by convention.) A set of unit matrices are also shown by arrows.

As the algebraic diagrams will get rather involved later on, it will be convenient to show only the four rectangular matrices C_m, C_j, and A^m, A^j [Fig. 6(B)], supplemented by two unit matrices. It will be understood from now on that the four rectangular matrices (boundary operators) are derived from the square connection matrix C and its inverse A by partitioning the latter.

The complete algebraic diagram of a linear network includes the partial and total impedance and admittance matrices Z and Y, as well as the partial and total connection matrices C and A. A rather complete diagram is shown in Fig. 7(A). The diagram shows some (but not all) of the vectors and matrices that appear in equation 3(C). A still more simplified form, to be used in most studies, is shown

All solenoidal and lamellar electromagnetic vectors also appear on the algebraic diagram as small arrows leading to the dots.

ALGEBRAIC DIAGRAM OF INTERCONNECTED STRUCTURE

Each q-network has an algebraic diagram identical with that of a linear network, except that the index 1 is replaced by q. When all q-networks are interconnected to form one structure, two neighboring vertical lines on their algebraic diagrams merge into one line, as shown in Fig. 8(A). The vertical arrows may be kept separate by the addition of unit arrows [Fig. 2(C)]. Both diagrams are simplified forms.

As mentioned before, all odd-dimensional networks are built of dielectric material and all even-dimensional networks are built of magnetic materials. It is emphasized that with an isolated q-network, no incidence matrix M is associated, only a connection matrix C or A.

INCIDENCE MATRICES M AND M^{-1}

Between two q-networks the incidence matrices M appear as horizontal lines. They are rectangular matrices, not square, and contain only $+1$, -1, and 0 elements. They show how the volume elements of two networks with different dimensions are interconnected. The incidence matrices are found as products of two boundary operators (partial connection matrices).

From Fig. 7(B) the two middle slant vectors give

$$M_2{}^1 = C_m{}^1 A_{2t}{}^J \quad | \quad M_{q+1}{}^q = C_m{}^q (A_{q+1}{}^J)_t \tag{7A}$$

$$M_2{}^1 = \begin{array}{c|cccc} & a & b & c & d \\ \hline 1 & 1 & & & 1 \\ 2 & -1 & 1 & & \\ 3 & & -1 & & -1 \\ 4 & -1 & & 1 & \\ 5 & & 1 & -1 & \\ 6 & & & -1 & -1 \end{array} \tag{7B}$$

The inverse of $M_2{}^1$ does not exist. But an equivalent inverse may be found by following (against the arrows) the inner two slant vectors. For instance:

$$(M_2{}^1)^{-1} = M_1{}^2 = C_j{}^2 A_{1t}{}^m$$

$$(M_{q+1}{}^q)^{-1} = M_q{}^{q+1} = C_j{}^{q+1} A_{qt}{}^m \tag{7C}$$

$$M_1{}^2 = \begin{array}{c|cccccc} & 1 & 2 & 3 & 4 & 5 & 6 \\ \hline a & & -1 & -1 & & & \\ b & & & -1 & & & \\ c & & & -1 & & -1 & \\ d & & & & & & \end{array} \tag{7D}$$

The product $M_2{}^1 M_1{}^2$ is not unity and the notation M^{-1} is probably not appropriate (only convenient).

Divided Differences

DEPENDENT VARIABLES

The stage is now set to introduce the electromagnetic waves. That is, hitherto the underlying topological structure was established and the next step is to superimpose an algebraic structure over it.

The set of dependent variables y_α (with n components) will be assumed as a set of bound magnetic poles $\dot{\rho}_m{}^{(b)o} = \dot{B}_\alpha{}^b$ placed on the 0-vertices. All quantities are assumed to be alternating (say at 60 cycles) so that

$$y_\alpha = \dot{B}_\alpha{}^0 = d\rho_m{}^{(b)}/d^\prime t \tag{8}$$

represents a generated voltage, as shown by a short arrow in Fig. 9.

When p set of dependent variables $y_\alpha{}^{(p)}$ exist, then $\dot{B}_\alpha{}^{0(p)}$ represents not a vector with n components, but p different vectors (that is, an $n \times p$ matrix).

FIRST-ORDER DIVIDED DIFFERENCES

The propagation of waves across the entire structure is shown on the flow diagram of Fig. 9 by heavy arrows. On each branch of the linear network appears a lamellar voltage:

$$\dot{\rho}_{m1}{}^{(f)} = E_1 = A_1{}^J C_{mt}{}^0 \dot{B}_0 = M_1{}^0 \dot{B}_0 = \operatorname{div} \dot{B}_0 \tag{9A}$$

In each branch both lamellar and solenoidal dielectric fluxes flow

$$\dot{d}^1 + \dot{D}^1 = \epsilon^{11} E_1 = \epsilon^{11} A_1{}^J C_m{}^0 \dot{B}_0 = \epsilon^{11} M_1{}^0 \dot{B}_0 \tag{9B}$$

representing the first-order divided differences (or rather, their contravariant form).

The total stored dielectric energy in the entire linear network is equal to the sum-of-squares of all first-order divided differences

$$\eta_1 = \Sigma E_1 \epsilon^{11} E_1 = \Sigma(\dot{d}^1 + \dot{D}^1)\epsilon_{11}(\dot{D}^1 + \dot{d}^1)$$
$$= \Sigma(\dot{d}^1 + \dot{D}^1) E_1 = \left(\frac{y_n - y_{n-1}}{x_n - x_{n-1}}\right)^2 \tag{9C}$$

(Strictly speaking, each divided difference is represented not by a flux, but by the square root of a stored energy. The conventional divided differences are not components of a tensor. More will be said about this point in a later paper.)

GEOMETRICAL INTERPRETATION

If the dependent variable y_α is considered to represent a surface over the $x_{(k)}{}^\alpha$ space, then the line integral of each dielectric flux in a branch represents the projection of the gradient upon a line, connecting two points of the y_α surface

Vol.
Pt. 1
1959

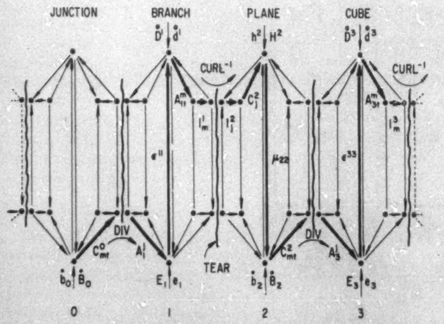

Fig. 9. Flow diagram of wave propagation in torn polyhedron; determination of divided differences

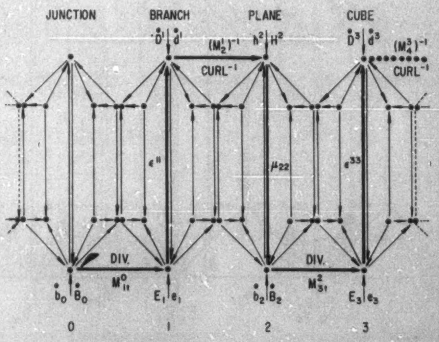

Fig. 10. Simplified flow diagram of open-circuit wave propagation

(not the slope of the surface itself). The higher order divided differences relate, in a complicated manner, the higher order divergences and curls ("exterior" derivatives[4,5]) with the planes and cubes of the polyhedron. For example:

$$\dot{b}_{q+1}+\dot{B}_{q+1}=\text{curl }(e_q+E_q) \tag{10}$$

The divided differences of the present paper are generalizations of those used in the calculus of finite differences, and should not be confused with derivatives.

SECOND-ORDER DIVIDED DIFFERENCES

On each plane (or on some of the planes only) of the planar network appears, according to the flow diagram

$$\begin{aligned} h^2&=C_{ji}^2A_1^J(\dot{d}^1+\dot{D}^1)\\ &=(M_2^1)^{-1}(\dot{d}^1+\dot{D}^1) \qquad \text{(11A)}\\ &=\text{curl}^{-1}(\dot{d}^1+\dot{D}^1)\end{aligned}$$

It should be noted that the path across the boundaries of the two q-networks is directed now against the incidence matrix M_2^1, requiring its inverse, which is, however, nonexistent (since M_2^1 is rectangular). This is the reason for the need of orthogonal network concepts: to open up otherwise nonexistent pathways of propagation.

Since the planes are assumed to be constructed of magnetic materials, the magnetic flux lines (lamellar and solenoidal) appearing across them are given by

$$\begin{aligned}\dot{b}_2+\dot{B}_2=\mu_{22}h^2&=\mu_{22}C_{ji}^2A_1^J(\dot{d}^1+\dot{D}^1)\\ &=\mu_{22}(M_2^1)^{-1}(\dot{d}^1+\dot{D}^1) \qquad \text{(11B)}\end{aligned}$$

representing the second-order divided differences (or rather their covariant form). Again the total stored magnetic energy represents their sum-of-squares:

$$\begin{aligned}\eta_2&=\Sigma h^2\mu_{22}h^2=\Sigma(\dot{b}_2+\dot{B}_2)\mu^{22}(\dot{B}_2+\dot{b}_2)\\ &=\Sigma h^2(\dot{B}_2+\dot{b}_2) \qquad \text{(11C)}\end{aligned}$$

HIGHER ORDER DIVIDED DIFFERENCES

One cycle of propagation has thus far been accomplished and the second cycle continues in the same manner with only the dimensions changed. In general, the steps are

$$\begin{aligned} &E_q=(M_q^{q-1})_t(\dot{B}_{q-1}+\dot{b}_{q-1})\\ &\dot{d}^q+\dot{D}^q=\epsilon^{qq}E_q=Y^{qq}E_q \qquad \text{(12)}\\ &h^{q+1}=(M_{q+1}^q)^{-1}(\dot{d}^q+\dot{D}^q)\\ &\dot{b}_{q+1}+\dot{B}_{q+1}=\mu_{q+1,q+1}h^{q+1}=Z_{q+1,q+1}h^{q+1}\end{aligned}$$

SUMMARY OF DIVIDED DIFFERENCES

The tensorial divided differences of successive order are calculated with the aid of the rectangular boundary operators and with the previous divided differences as follows:

1. $\Delta y/\Delta x=\dot{d}^1+\dot{D}^1=\epsilon^{11}A_1\dot{D}^JC_m^0\dot{B}_0$ $=\epsilon^{11}M_1^0\dot{B}_0$
2. $\Delta^2y/\Delta x^2=\dot{b}_2+\dot{B}_2$ $=\mu_{22}C_{ji}^2A_1^J(\dot{d}^1+{}^1\dot{D})$ $=\mu_{22}(M_2^1)^{-1}(\dot{d}^1+\dot{D}^1)$
3. $\Delta^3y/\Delta x^3=\dot{d}^3+\dot{D}^3$ $=\epsilon^{33}A_3^JC_m^2(\dot{b}_2+\dot{B}_2)$ $=\epsilon_{33}M_3^2(\dot{b}_2+\dot{B}_2)$ (13)
4. $\Delta^4y/\Delta x^4=\dot{b}_4+\dot{B}_4$ $=\mu_{44}C_{ji}^4A_3^J(\dot{d}^3+\dot{D}^3)$ $=\mu_{44}(M_4^3)^{-1}(\dot{d}^3+\dot{D}^3)$

The total stored energy in each q-network is equal to the sum-of-squares of the qth order divided differences.

With one set of dependent variables y_α, each divided difference is a vector. Their calculation involves products of a matrix with a vector. With several sets of $y_\alpha^{(p)}$ each divided difference is an $n\times p$ matrix (p different vectors).

All covariant ϵ_{pp} or μ_{qq} may be denoted as Z_{pp} or Z_{qq} and all contravariant ϵ^{pp} or μ^{qq} may be denoted as Y^{pp} or Y^{qq}. The incidence matrices M_p^q and their inverse $(M_p^q)^{-1}$ represent either divergence or curl operators. A simplified flow diagram for the calculation of the divided differences in terms of M's and Z's is shown in Fig. 10. It is emphasized that different problems require slightly different definitions for the divided differences.

CYCLES OF CREATION AND ANNIHILATION

The following interesting facts should be noted concerning the nature of propagation of waves.

1. In passing to the next higher dimension in a horizontal direction the transverse (solenoidal) waves or the longitudinal (lamellar) waves alternately disappear.
2. In propagating across the material network in a vertical direction a missing portion of the wave reappears.
3. After each two dimensions the cycle of annihilation and creation of an entire electromagnetic wave repeats itself.

The reason for the cyclic zig zag shape of the flow diagram in Fig. 9 is the fact that two successive differentiations cancel a wave entirely. Familiar examples of such cancellations are

$$\text{div curl}\Phi=0 \mid \text{curl grad}\Phi=0 \tag{14A}$$

A generalization of the divergence and curl concepts in simply connected spaces is the concept of "exterior" differentiation arising in multiply connected spaces[4,5] used here. Two successive exterior differentiations give

$$dd\Phi=0 \mid M_q^{q-1}M_{q+1}^q=0 \tag{14B}$$

(In the present example the differential operator d is represented by a rectangular incidence matrix M.)

THE METRICS OF DE RHAM AND HODGE

With the artifice of introducing material constants $\epsilon_{\alpha\beta}$ and $\mu_{\alpha\beta}$ as metric tensors and zigzagging between covariant and contravariant spaces, the entire sequence of networks has been populated with transverse and longitudinal electromagnetic waves.

Unfortunately the geometrical or physical analogs of the concepts of impedance tensor $Z_{\alpha\beta}$ and admittance tensor $Y^{\alpha\beta}$ do not appear in the works of De Rham[4] or Hodge[5] nor in Misner and Wheeler[3] in spite of the introduction of metrics into their spaces (generalized polyhedron). These writers use the metric tensor for introducing isomorphism between the primary and dual wave quantities that arise in relativity physics and not for introducing ϵ and μ into the underlying space. Of course, these writers do not introduce any cyclicly repetitive wave propagation either. The latter is an artifice needed for a nonuniform calculus of finite differences and is not likely to arise in nature or in geometry.

Inductance of A-C Magnets from Simple Models

J. F. H. DOUGLAS
FELLOW AIEE

R. J. VOITH
NONMEMBER AIEE

THE INDUCTANCE of an a-c magnet is a function of its coil as well as its magnetic structure. Hence, if the total equivalent permeance of the magnetic field is known, the inductance can be obtained from the equation

$$L = N^2 \mathcal{P}_{eq}(10^{-8}) \qquad (1)$$

where

L = inductance, henrys
N = series turns in the coil
$\mathcal{P}_{eq}$ = equivalent permeance, lines/ampere

Because computing the permeance of even very simple fields is at best a laborious process, the permeance is generally most easily obtained from experimental tests on models. This paper describes a method in which the field of an a-c magnet is divided into a particular set of hypothetical components which can be simulated electrically with simple models. The permeance of each component field is obtained from a model which suits the component field, and the several permeances so obtained are superimposed to yield the permeance of the original field.

Since there are, in general, fields which satisfy Laplace's equations and those which do not, two kinds of models are used. A component field which has a potential function at all points may be simulated by an electroconducting analog model, while a component field which has no potential function must be simulated with a model having a coil and iron parts, or else found by a close mathematical approximation. Both kinds of models are used in this work. However, in stating that the several component fields may be found from models, the mathematical solution of a particular component field is not excluded as a less desirable method. Occasionally a particular component field can be easily computed with sufficient accuracy and one such example is given in Appendix I.

In order to furnish a check on the accuracy of the method and the applicability of the models described in this paper, the specifications of a prototype magnet were used in constructing the models. Tests were then conducted on the prototype magnet which furnished the basis of comparison.

Component Fields of an A-C Magnet

According to the principle of superposition, a magnetic field may be separated into several hypothetical components for purposes of analysis if no saturation is present. It was assumed that the magnet selected for this work operated at flux densities low enough to satisfy this requirement. Fig. 1 shows a sketch of the prototype magnet used in this work. It is a solenoid plunger magnet having an *E*-shaped structure. A movable plunger seals on one part of the *E* frame and is separated from the outside legs of the *E* frame by a minor air gap.

The field of the magnet is separated into three components which are to be measured from analog and direct models. These fields are indicated in Fig. 2. The first component field results from a current sheet surrounding the plunger. This current sheet is indicated by the heavy lines shown in Fig. 2(A). The height of the current is designated as p, and is seen to be a function of plunger position and consequently a function of the major gap g. The equivalent permeance of the field produced by the current sheet just described is designated as $\mathcal{P}_p$. A current sheet surrounding the major air gap, indicated by the heavy lines in Fig. 2(B), produces the second component field. The height of the current sheet is equal to g, and the equivalent permeance of the field associated with this current sheet is designated as $\mathcal{P}_g$.

The two current sheets described in the foregoing are inductively coupled, giving rise to a third component field, whose permeance is designated as $\mathcal{P}_m$. The mutual permeance $\mathcal{P}_m$, however, is not designated as a major component because it is indirectly determined from other permeances. A detailed discussion of $\mathcal{P}_m$ is deferred to a later part of this paper.

The third major component field results from the magnet coil itself and a balancing current sheet as shown in Figure 2(C). Relative instantaneous polarities of the currents are indicated by the dot-cross symbols on the sketch. The balancing current sheet has a height h, equal to the coil height, and is related to the heights of the current sheets surrounding the major gap and the plunger respectively, by the equation

$$h = g + p \qquad (2)$$

The equivalent permeance of the field resulting from the magnet coil and its balancing current sheet is designated as $\mathcal{P}_w$.

When the component fields described in the foregoing are combined by superposition they leave as their total sum the field of the prototype magnet.

Development of the Analog Model

The fields resulting from the current sheets surrounding the plunger and the major gap are Laplacian fields and can be simulated by electroconducting analog models. Before discussing in detail how a particular model can be constructed to simulate such a field, a brief discussion of the general correspondence between electrical and magnetic phenomenon is in order.

In its simplest form, Ohm's law for electric circuits can be written as

$$G = I/V \qquad (3)$$

where

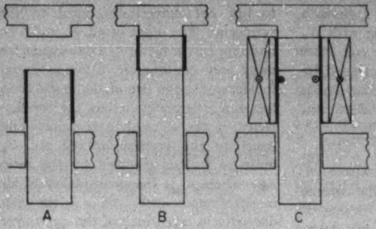

Fig. 2. Fields of magnet

A—Current sheet surrounding plunger
B—Current sheet surrounding major gap
C—The magnet coil and its balancing current sheet

V = potential difference, volts
I = current, amperes
G = conductance of the medium, mhos

Ohm's law for magnetic circuits can be written as

$$\mathcal{P} = \phi/U \tag{4}$$

where

ϕ = flux, webers
U = magnetic potential difference, ampere-turns
$\mathcal{P}$ = permeance of the medium, henrys

Because the equations previously given are identical in form, it is apparent that conductance in an electric circuit is the analog of permeance in a magnetic circuit. It is also apparent that current and potential difference in the electric circuit are respectively the analogs of flux and potential difference in the magnetic circuit. Hence, if a correspondence can be established between ϕ and U in the magnetic circuit and I and V respectively in an equivalent electric circuit, then the electrical quantities may be measured, the conductance computed, and the permeance in the magnetic circuit obtained by analogy.

The manner in which a correspondence between these quantities is effected for the component field resulting from the current sheet surrounding the plunger, will now be described.

Symmetry of the Field

An inspection of Fig. 1 shows that the field of the magnet, as well as all component fields, possess planes of symmetry. The planes designated as AA' and BB' divide each field into four identical parts. Since the equivalent permeance of one of its identical parts differs from the equivalent permeance of the entire field by only a constant multiplier, only one quarter of the field was simulated in constructing the analog models Quadrant III in Fig. 1 shows which quarter of the field was selected in constructing the electroconducting analog models.

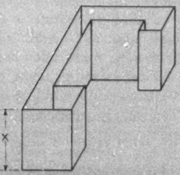

Fig. 3. Model frame

The Conducting Medium

If the field produced by current sheet surrounding the plunger is to be simulated electrically, several things must be accomplished. First, all flux paths in the magnetic field must be replaced by conducting media. Since flux does not wholly confine itself to its intended ferromagnetic circuit, this includes the space surrounding the magnetic structure as well. Secondly, the magnetic potential distribution along the plunger must be known, and a means of duplicating it electrically must be found. And third, a means of accounting for partial flux-linkages in determining the equivalent permeance must be discovered. The second and third of these are accomplished with the aid of a special transformer. The first is accomplished as follows.

Magnetic flux in the magnet exists in two possible media. One medium consists of the ferromagnetic parts of the magnet, that is, its frame and plunger. The other medium consists of the minor and major air gaps and all leakage paths. The permeability of the latter medium is designated as μ_0, and is equal to 3.19 lines/ampere-inch. The permeability of the ferromagnetic medium is by comparison a very large number and is assumed to be infinite. An electroconducting analog model can be effected in this instance by constructing a scale model of the frame out of a material having a very low value of resistivity. The model could then be immersed in an electrolytic bath, thus furnishing the second medium corresponding to the nonferromagnetic space in and around the magnet. If the approximation regarding the permeability of the core in the magnet is to hold in the model, then the resistivity of the model frame must be sufficiently low so that the potential difference between any two points on the frame can be assumed to be zero. In this work the model frame was fabricated from sheet steel as shown in Fig. 3. The model corresponds to that portion of the magnet contained in quadrant III in Fig. 1 since only one quarter of the field is being considered. To facilitate construction and subsequent electric connections, the model was built to a scale k times as large as the magnet. The corresponding reduction in permeance is accounted for by the same factor. The dimension X in Fig. 3 was made larger than required so that the model could be immersed in the electrolyte to its proper depth without submerging the entire model, thus providing easy access to the model during testing.

The Magnetomotive Force Function

The second step in constructing the model is that of simulating the magnetic potential along the current sheet surrounding the plunger. The magnetic potential on the surface of the plunger under the current sheet varies linearly with distance along the plunger as indicated by the straight line graph in Fig. 4. An approximation to this linear potential function is indicated by the step function on the same graph. Obviously, the greater the number of steps, the closer the approximation. Such a potential function was obtained by constructing the model plunger with thick steel laminations, insulated from one another at equal intervals, thus dividing the plunger into sections, and exciting each section from the secondary of a trans-

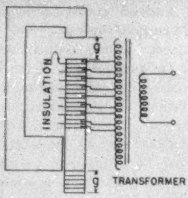

Fig. 5. Transformer connections to segments on model plunger corresponding to a major gap of g inches

former having a sufficient number of equispaced taps as shown in Fig. 5. In order to match the "half steps" at each end of the potential function, each section was made up of two laminations as shown in Fig. 5. The several sections which have been removed to form the major gap have been added to the opposite end of the plunger in order to account for the fact that the plunger actually extends beyond the frame as the gap opens. This artifice is necessary because the fringe permeance of the minor gap is a function of plunger position. The plunger segments were insulated from one another by thin Bakelite laminations which protrude slightly from the plunger surface as indicated in Fig. 5. The amount of protrusion is vital since if the insulation projects too much, the measured conductance will be too small, and vice versa. There are several methods by which the correct projection of the insulation from the plunger surface could be found, such as graphical or experimental mapping or the Schwartz-Cristoffel theorem. An experimental method involving a two-dimensional model cut from conducting paper was used in this work. The procedure is described in Appendix II.

Partial Flux Linkages

The model which is to represent the component field resulting from the current sheet surrounding the model plunger is now complete, and it remains only to be shown that its conductance actually corresponds to the permeance of the field and how the conductance can be measured for any plunger position. An expression for the equivalent permeance $\mathcal{P}_p$ of the field will not be derived by computing the inductance of the current sheet shown in Fig. 4. Assume that the current sheet is comprised of a current ribbon of differential thickness but finite width and is formed by winding the ribbon around the plunger in the manner of a coil. Assume further that the coil so formed has N turns. Fig. 4, shows a small tube of flux $\Delta\phi_n$ linking with N_n of the N turns in the current coil. Let the permeance of the path occupied by $\Delta\phi_n$ be $\Delta\mathcal{P}_n$. Then from equation 1, the inductance ΔL_n resulting from $\Delta\phi_n$ linking with N_n turns is given as

$$\Delta L_n = \Delta\mathcal{P}_n(N_n)^2(10^{-8}) \tag{5}$$

The total inductance L_p, of the current sheet, is then given to any degree of approximation by the following equations

$$L_p = \sum_{n=1}^{m} \Delta L_n = \sum_{n=1}^{m} \Delta\mathcal{P}_n(N_n)^2 10^{-8}$$
$$= \mathcal{P}_n N^2 10^{-8} \tag{6}$$

where $\mathcal{P}_{ps}$ is the total equivalent permeance of the field. Dividing equation 6 by $N^2(10^{-8})$ results in the following expression for $\mathcal{P}_p$

$$\mathcal{P}_p = \sum_{n=1}^{m} \Delta\mathcal{P}_n(N_n/N)^2 \tag{7}$$

Consider now the model which has been constructed to simulate the field produced by the current sheet surrounding the plunger. The ferromagnetic parts of the magnet have been replaced by a virtual short circuit to electric potential. The nonferromagnetic space has been replaced by an electrolyte. The linear magnetic potential along the plunger has been replaced by an approximate step potential which is obtained from the secondary of a transformer having large number of equally spaced taps. Consider the load on the secondary of the transformer. A tube of current Δi_n (analogous to the tube of flux shown in Fig. 4) links with N_n turns of the transformer secondary. Assume that the path occupied by Δi_n has a conductance ΔG_n. The conductance ΔG_n seen from the primary side of the transformer would appear as $\Delta G_n(N_n/N)^2$ provided the number of turns in the primary is N. Since all of the current tubes so defined are in parallel, the total conductance G_p seen from the primary side of the transformer is the sum

$$G_p = \sum_{n=1}^{m} \Delta G_n(N_n/N)^2 \tag{8}$$

A comparison of equations 7 and 8 shows that they are identical in form, and hence the analogy is complete. Therefore, when the electric input to the transformer primary is measured and the equivalent conductance computed, the equivalent permeance of the field is obtained by analogy.

The conductance G_p is proportional to but not numerically equal to the permeance $\mathcal{P}_p$. First of all, G_p must be multiplied by a factor $4/k$ to account for using only one quarter of the field and for increasing the size of the model by a factor k. Secondly, unless the conductivity of the electrolyte is numerically equal to the permeability of air, G_p must be further modified by the ratio μ_0/σ where μ_0 is the permeability of air in lines/ampere-inch, and σ is the conductivity in mhos/inch of the electrolyte used in the model. Hence

$$\mathcal{P}_p = k\mu_0 G_p/4\sigma = k\mu_0\rho\,\frac{G_p}{4} \tag{9}$$

where ρ is the reciprocal of σ or the resistivity of the electrolyte in ohm-inches.

The conductance equation 8 matches the permeance equation 7 exactly. However, the degree to which $k\mu_0\rho G_p/4$ approximates numerically the true equivalent permeance of the field depends on the number of steps used in approximating the potential function on the plunger. In this work it was estimated that the minimum number of steps which resulted in a negligible error was ten.

Circuitry and Measurements

The equivalent permeance $\mathcal{P}_p$, of the component field as obtained from equation 9, is shown in Fig. 6 plotted against the air gap in the prototype magnet. $\mathcal{P}_p$ is of course a function of plunger position. Hence, a series of data must be taken during which the model is modified to simulate different plunger posi-

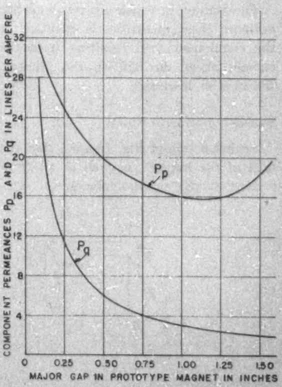

Fig. 6. Permeances $\mathcal{P}_p$ and $\mathcal{P}_q$ of fields produced by current sheets surrounding plunger and major gap respectively

tions, or what is the same thing, different values of major gap. Fig. 5 shows the model adjusted to simulate the plunger position corresponding to a gap of g inches. The gap has been simulated by removing the transformer excitation from the sections which make up the length g, and physically moving the laminations to the opposite end of the plunger. When the laminations are placed on the opposite end of the plunger, the insulation between sections must, of course, be removed. The number of plunger positions which can be simulated in this manner is obviously limited to the number of sections making up the plunger.

The circuitry used in measuring the conductance G_p is shown schematically in Fig. 7. When switch S is placed in position 1, the wattmeter W reads the power into the transformer and the voltmeter V reads the voltage across the primary winding. If for a particular plunger position on the model the wattmeter and voltmeter readings are respectively W_1 and V_1, then the conductance G_{p1} is given as

$$G_{p1}=(W_1-P_1)/V_1^2=W_1'/V_1^2 \qquad (10)$$

where P_1 is the core loss in the transformer at the voltage V_1, and W_1' is the corrected power.

If the voltage or power lost in the transformer windings is not negligible, it will be necessary to further adjust the measured quantities in order to obtain the correct value for G_p. In this work the copper loss was taken into account by substracting from W_1' the quantity $(W_1/V_1')^2(R_1+a'R_2)$ before using it in equation 10. R_1 and R_2 are respectively the total primary and secondary resistance of the transformer windings in ohms, and a' is the variable ratio of the total primary turns to secondary turns used in exciting the model. When the switch S is placed in position 2, V and W read respectively the power and voltage to the device called the "calibrating cell" in Fig. 7. The calibrating cell is a device used to keep a running check on the resistivity of the electrolyte. It consists of a hollow tube of insulating material with a conducting plate at each end of the tube. The tube contains several small holes which allow it to become filled when immersed in the electrolyte and to drain when removed. If the inside dimensions of the cell are known, it contains a known volume of electrolyte when immersed, and if the conductance of this volume can be measured the resistivity of the electrolyte can be computed from the equation

$$\rho=A_e/G_e l \qquad (11)$$

where

ρ=resistivity of the electrolyte, ohm-inches
G_e=conductance, mhos of the electrolyte contained in the cell
l and A_e=inside dimensions of the tube, inches and square inches respectively

The conductance of the cell is obtained by dividing the square of the voltage drop across the cell into the power consumed by the cell. Hence, in this manner the resistivity of the electrolyte was checked immediately after each reading was taken on the model, thus avoiding errors due to variations resulting from changes in temperature and from settling. The electrolyte used in these experiments was a solution of sodium carbonate (Na_2CO_3) concentrated to approximately one part normal solution in 60 parts of water.

Component Permeance $\mathcal{P}_q$

The permeance of the component field resulting from the current sheet surrounding the major gap shown in Fig. 2(B) is obtained partly by calculation and partly by experimentation. If it is again assumed that no ampere-turns are consumed in the iron parts of the magnet, the equivalent reluctance of this field consists of the reluctance of the major gap in series with the reluctance of the minor gap and its fringe area. The field inside the current sheet is regular and uniform and its reluctance $\mathcal{R}_g$ can be computed from the formula

$$\mathcal{R}_g=g/\mu_0 A \qquad (12)$$

where g and A are the gap dimensions of the major gap in inches and square inches respectively, and μ_0 is the permeability of air in lines/ampere-inch. The reluctance $\mathcal{R}_f$ of the minor gap and its fringe is not a fixed quantity but is a function of plunger position. As the plunger moves out from its position at zero gap the proximity of iron at the minor gap changes thus altering the field and hence its reluctance.

The reluctance $\mathcal{R}_f$, or its reciprocal $\mathcal{P}_f$, can be obtained in a manner similar to the way $\mathcal{P}_p$ was obtained, using the same model with one modification. It will be observed that in the model used to determine $\mathcal{P}_p$, the permeance at zero gap is equal to $\mathcal{P}_f$. This is true since all sections making up the plunger are in place and under excitation from the transformer secondary, and hence, no major gap exists in the model and the entire electromotive force is consumed in the minor gap and its fringe area.

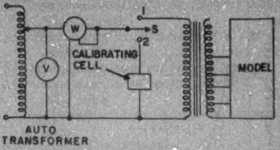

Fig. 7. Circuit used for testing analog models

The variation in $\mathcal{R}_f$ with gap length may be simulated by adding laminations to the model plunger, thus extending the plunger beyond its position at zero gap without actually creating a major gap by removing laminations from the plunger proper. Thus, the reluctance obtained from electrical quantities measured on the primary side of the transformer in the usual manner is the reluctance of the minor gap and its changing fringe only.

The accuracy of the procedure described with the foregoing for obtaining $\mathcal{R}_f$ may be questioned since the presence of a major gap may in fact change the reluctance. However, since $\mathcal{R}_f$ is a very small percentage of the total reluctance, an error can be tolerated in $\mathcal{R}_f$ without introducing an appreciable error in the total reluctance, and therefore the procedure was not checked as a major source of error. The total equivalent reluctance $\mathcal{R}_q$ of the component field is the sum of $\mathcal{R}_f$ and $\mathcal{R}_g$, and the equivalent permeance $\mathcal{P}_q$ of this field is therefore the reciprocal of $\mathcal{R}_q$. In terms of the reluctances given previously

$$\mathcal{P}_q=1/\mathcal{R}_q=1/(\mathcal{R}_g+\mathcal{R}_f) \qquad (13)$$

The permeance $\mathcal{P}_q$ is shown as a function of the air gap in the prototype magnet in Fig. 6.

Mutual Permeance

As stated earlier the two current sheets surrounding the plunger and the major gap give rise to component fields which are mutually coupled, and therefore their permeances as just obtained must be adjusted to account for this fact. It was also stated previously that the two current sheets were electrically connected in series with their fields reinforcing one another. The equivalent inductance L_t of such a system is given as

$$L_t=L_q+L_p+2M \qquad (14)$$

where the subscripts q and p have their previous significance and M is the mutual inductance in henrys. The individual inductances in equation 14 are functions of field permeance and may be replaced by their respective permeances provided

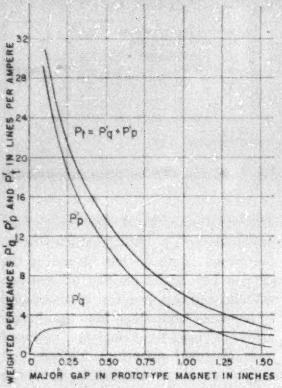

Fig. 8. Permeances $\mathcal{P}_p$ and $\mathcal{P}_p$ modified to account for mutual inductance between current sheets

a suitable weighting factor corresponding to N^2 in equation 1 can be found.

Assume for the moment that the current sheets surrounding the major gap and the plunger have a finite number of turns given as N_q and N_p respectively and that the total turns of the two coils thus formed is N_t. In accordance with elementary circuit theory, the terms in the right hand member of equation 14 may be transformed as follows

$$L_t = N_q^2\mathcal{P}_q + N_p^2\mathcal{P}_p + 2N_qN_p\mathcal{P}_m \qquad (15)$$

Now if equation 15 is divided by N_t^2, the left-hand member becomes the total equivalent permeance $\mathcal{P}_t$ of the two fields acting together, and the terms in the right-hand member become their respective field permeances modified by an appropriate turns-ratio. That is

$$\mathcal{P}_t = (N_q/N_t)^2\mathcal{P}_q + (N_p/N_t)^2\mathcal{P}_p + 2N_qN_p\mathcal{P}_m/N_t^2 \qquad (16)$$

Since the turns-rations in equation 16 in reality represent ratios of linear current distribution, they may be replaced by ratios of their respective heights. Making use of the relationship and symbols defined in equation 2, equation 16 can be written

$$\mathcal{P}_t = (g/h)^2\mathcal{P}_q + (p/h)^2\mathcal{P}_p + 2qp\mathcal{P}_m/h^2 \qquad (17)$$

In determining the mutual inductance of the system previously described, one might reasonably conclude that practically all of the flux produced by the current sheet surrounding the major gap links with current sheet surrounding the plunger since the latter is terminated on either end by iron. If it can be assumed that the current sheet surrounding the major gap produces no leakage flux, it follows that $\mathcal{P}_m = \mathcal{P}_q$ in equation 17. Making this substitution reduces equation 17 to

$$\mathcal{P}_t = p_q' + \mathcal{P}_p' \qquad (18)$$

where

$$\mathcal{P}_q' = (g/h)(2 - g/h)\mathcal{P}_q \qquad (19)$$

and

$$\mathcal{P}_p' = (p/h)^2\mathcal{P}_p \qquad (20)$$

The three permeances $\mathcal{P}_q$, $\mathcal{P}_p$, and $\mathcal{P}_t$ are shown in Fig. 8 as a function of the major air gap in the prototype magnet.

Component Permeance $\mathcal{P}_w$

The remaining permeance to be considered is that of the field resulting from the magnet coil and its balancing current sheet shown in Fig. 2(C). Because of the presence of current, the resulting magnetic field is nonLaplacian. Hence, an electroconducting analog model cannot be used since no potential function can be specified. In this case the permeance is determined from electrical measurements made on a suitable model which generates the field directly. The model used therefore, is not an analog model, but merely a test model using iron and copper.

The test model was formed by constructing a special 3-winding coil having N_w turns in each winding. Winding *1* was placed on a Bakelite block having dimensions proportional to the prototype plunger. This winding was closely wound with fine wire no. 26 Awg (American Wire Gage) so as to approximate a current sheet on the plunger surface. A Bakelite frame having outside dimensions proportional to the inside dimensions of the prototype coil was then placed around winding *1*. Two strands of no. 14 Awg wire were then wound together on the outer Bakelite frame forming two curls. Each curl had the same number of turns as winding *1*.

The active winding (winding *2*) corresponds to the prototype coil, and the remaining winding (winding *3*) was utilized as a test winding. For convenience the model was made k_w times as large as the prototype. The 3-winding coil described in the foregoing was then placed inside a laminated iron frame having dimensions k_w times those of the prototype but with no plunger. Winding *1* and winding *2* were then connected in series so as to oppose one another and the series combination energized from a 60-cycle source. The resulting voltage induced in winding *3* was measured with a vacum tube voltmeter. The voltage induced in winding *3* results from leakage flux between the thin coil *1* and the thick coil *2*. Hence the ratio of this voltage to the angular velocity times the current in windings *1* and *2*, is the leakage inductance L_w or the equivalent inductance of a thick coil and its balancing current sheet. The equivalent permeance $\mathcal{P}_w$ is then given as

$$\mathcal{P}_w = L_w(10^8/N_w^2k_w) \qquad (21)$$

The permeance $\mathcal{P}_w$, obtained by the method described was 2.8 lines/ampere for the prototype.

Since the coil and balancing current sheet produces no field inside the current sheet, the permeance obtained in the manner described would be the same regardless of what was inside the current sheet, hence, the plunger was omitted in constructing the test model. However, in the prototype model the partial flux (which the test model generates) is not restricted to paths parallel to the plunger, and in fact may be shorter in length when the plunger is present inside the coil. The permeance $\mathcal{P}_w$ can therefore be expected to be a function of plunger position, decreasing slightly with increasing air gap to a minimum of 2.8 lines/ampere at maximum gap. Since $\mathcal{P}_w$ was assumed constant in this work, the minimum value of 2.8 lines/ampere was selected so as to introduce the least error in the total permeance. In other words, permitting the largest error in $\mathcal{P}_w$

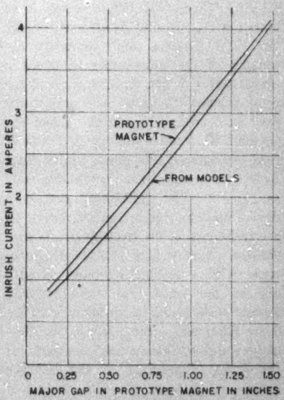

Fig. 9. Inrush current as determined from tests on models and by measurement on prototype magnet

to occur where $\mathcal{P}_w$ is the smallest percentage of the total permeance. A reasonably close approximation to $\mathcal{P}_w$ can easily be obtained mathematically with the aid of several simplifying assumptions as shown in the Appendix I.

The total equivalent permeance of the prototype magnet is given as

$$\mathcal{P}_{eq}=\mathcal{P}_t+\mathcal{P}_w \tag{22}$$

and is identical in shape to the curve $\mathcal{P}_t$ shown in Fig. 8 since $\mathcal{P}_w$ is a constant.

Comparison of Results with Prototype

In order to afford a simple means of comparison, the inrush current of a magnet whose field has the permeance given in equation 22 is computed from the following equation

$$I_r=E(R^2+X_{eq}^2)^{-1/2} \tag{23}$$

in which X_{eq} has the value

$$X_{eq}=2\pi fL_{eq}=2\pi N_w^2(10^{-8})\mathcal{P}_{eq} \tag{24}$$

where

E=rated voltage of the prototype magnet
N_w, R=number of turns and the resistance in ohms, respectively, of its coil
f=frequency of the applied voltage
I_r=inrush current, amperes

The inrush current calculated in the manner described is shown in Fig. 9 along with the inrush current actually measured on the prototype magnet. The discrepancy between the two curves at any value of gap is less than 10% of the inrush current. Some discrepancy is to be expected since the ampere-turns consumed in the iron were neglected in computing the current. It is estimated that neglecting the ampere-turns consumed in the iron results in an error of approximately 0.1 ampere. This cuts the discrepancy in Fig. 9 to about one half.

Conclusion

A fair degree of agreement between tests on the models and the prototype is to be noted. The discrepancies indicate the need for further study and experiment. The results indicate also that the analysis of other three-dimensional field problems using the artifice of current sheets might be worthy of investigation.

Nomenclature

A=area of major gap, inches^2
A_c=area of calibrating cell, inches^2
E=rated voltage of prototype coil, volts
G=conductance, mhos
G_c=conductance of calibrating cell, mhos
G_p, G_{pi}=equivalent conductance of field due to plunger current sheet, mhos
I=current, amperes

σ=conductivity of electrolyte, mhos/inch

Appendix I

Computed Value of Permeance $\mathcal{P}_w$

Fig. 10 shows a sketch of the magnet coil and its balancing current sheet along with the assumed flux density distribution in a plane passing through the axis of the coil. The flux is assumed to exist in straight lines parallel to the axis of the coil and having a length H-δ, where δ must be chosen on the basis of experience or experiment. The permeance $\mathcal{P}_{wc}$ of that portion of the field between the coil and the current sheet can be written down immediately as

$$\mathcal{P}_{wc}=\mu_0(cd+ab)/(H-\delta) \tag{25}$$

since in this region the flux density is uniform and the flux links completely all of the turns of the coil. The permeance of the differential tube of width dx shown in Fig. 10(A) is given as

$$d\mathcal{P}_{wp}=\mu_0(x/T)^2(1-2\pi x)dx/(H-\delta) \tag{26}$$

where x/T gives the ratio of turns linked by the tube to the total turns in the coil, and l is the length of the outside perimeter of the coil and is equal to

$$1=2(c+d)+2\pi T \tag{27}$$

The permeance of that portion of the field inside the coil is therefore this integral of $d\mathcal{P}_{wp}$ between the limits of $x=0$ and $x=T$.

$$\begin{aligned}\mathcal{P}_{wp}&=\int_0^T\mu_0(x/T)^2(1-2\pi x)dx/(H-\delta)\\&=\mu_0T(1/3-2\pi T/4)/(H-\delta)\end{aligned} \tag{28}$$

The total permeance is then the sum of $\mathcal{P}_{wc}$ and $\mathcal{P}_{wp}$ given in the foregoing that is

$$\mathcal{P}_w=\mathcal{P}_{wc}+\mathcal{P}_{wp} \tag{29}$$

Taking the dimensions given in Fig. 1, and $\delta=0$, $\mathcal{P}_w$ has the value 2.69 lines/ampere. The value of 2.8 lines/ampere obtained experimentally for $\mathcal{P}_w$ indicates that δ is 3.89% of H.

A—Field alone showing three insulating laminations
B—Step potential
C—Uniformly varying potential

Appendix II

The magnetic potential varies uniformly along the surface of the plunger in the prototype magnet, but the analogous electric potential in the analog model varies in finite steps as shown in Fig. 4. The sections of the model plunger are insulated from one another by thin laminations of Bakelite which protrude slightly from the surface of the iron. If the length which these laminations protrude from the surface is selected properly, the resistance of the field resulting from the step potential can be made equal to the resistance of the field due to a uniformly varying potential. In the discussion which follows it is assumed that the proper length can be found on the basis of a two-dimensional analysis.

A portion of the model plunger showing three insulating laminations which are exaggerated in thickness is shown in a plane perpendicular to the plunger surface in Fig. 11(A). The component of the electric field intensity E_y perpendicular to the plunger surface is not affected by the length y of the protruding insulation. The protrusion y does however affect the field E_x parallel to the plunger surface. If the field E_x is considered alone, a plane perpendicular to the plunger surface contains the equipotential lines *jab*, *hc*, *fed*, and the flow lines *bcd* and *ajigfe* as shown in Fig. 11(A). A two dimensional model of a field having boundaries described by the equipotential and flow lines previously cited can be made out of conducting paper as shown in Fig. 11(B) where the edges *jab* and *fed* have been painted with silver conducting paint. The resistance R_f between the equipotential lines of the model can be determined as a function of the protrusion y. The resistance R_u of a field due to a uniformly varying potential rather than a step potential can be obtained from the model shown in Fig. 11(C) in which *ab* and *cd* are equipotential lines and *bd* and *ad* are flow lines. If the resistance R_u is equal to the resistance R_f, there is no difference between the step potential on the model and the linear potential on the prototype plunger as far as the equivalent resistance or reluctance is concerned.

Since the resistance R_f is a function of the cut y (which corresponds to the amount of protrusion of the insulation into the electrolyte), R_f can be made equal to R_u by adjusting y to its proper length by a trial and error process. It was found experimentally by the foregoing method that the amount which the insulation should protrude into the electrolyte was 56% of the dimension *aj*.

◆

Discussion

Thomas J. Higgins (University of Wisconsin, Madison, Wis.): This paper is most interesting. It provides yet another striking illustration of the value of electrolytic tank and of conducting paper analog procedures in gaining solution of problems of current interest in industry, which are rather intractable to quick solution by analytic procedures.

In particular, the use of current sheets for separating non-Laplacian from Laplacian components, and the use of boundaries with step function potential to replace a linear variation of potential, may afford convenient analog solutions in many cases.

J. F. H. Douglas and **R. J. Voith:** While paper models can be used to solve some field problems in and outside copper windings, we were unable to find any conducting model to measure our third component of field. We conclude that the method we used will have to suffice until such conducting models are found.

Although the inductance of a magnet is related to its force-stroke curve, we did not discuss this topic in the paper because there seems to be no one generally accepted method of measurement. The three experimental methods and the calculated values from our tests differed materially from each other.

We wish to say in conclusion that force-stroke curves are important. Standards of measurement should be set up and further analytic studies should be made so that practical designs can be made.

A New Direct Matrix Inversion Method

R. BRUCE SHIPLEY
FELLOW AIEE

DOROTHY COLEMAN
NONMEMBER AIEE

THIS PAPER describes a special-purpose matrix inversion technique developed in the System-Planning Branch of TVA (Tennessee Valley Authority). This is the first known use of the method. It is particularly applicable to the inversion of matrices that describe power system impedances or admittances. As outlined, the technique is not entirely general. It requires division by elements of the major diagonal. Thus, when the element is being used as a divisor, it must not be zero. Under such a condition the digital program changes the sequence of calculations. However, a zero in the final diagonal position to be used will cause the matrix to be considered singular. The technique can be made more general but this is not necessary for most power system work.

Special Application

Power transmission system matrices are usually large, contain complex numbers, are symmetrical about the major diagonal, and have nonzero elements along the diagonal which are larger than the off-diagonal elements. The admittance matrix frequently contains zeros in about 90% of the off-diagonal terms.

Advantage is taken of these special characteristics to gain computer speed and to reduce the high-speed memory requirements. This is partially accomplished by storing only the diagonal and one half of the nondiagonal elements. Only one half of the nondiagonal elements are calculated and zero recognition is used to improve speed. The method is believed to be faster than other methods available to the industry.

Inversion of such matrices is desirable in economic studies, short-circuit studies, equivalent circuit studies, etc.

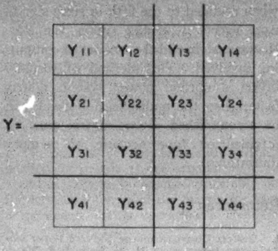
The Method

To clarify the explanation an entire matrix will be used rather than only one

---

Paper 59-502, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Southeast and South Central District Meeting, Atlanta, Ga., April 8-10, 1959. Manuscript submitted December 18, 1958; made available for printing February 13, 1959.

R. Bruce Shipley and Dorothy Coleman are with the Tennessee Valley Authority, Chattanooga, Tenn.



$$Y=\left[\begin{array}{cc|c|c} Y_{11} & Y_{12} & Y_{13} & Y_{14} \\ Y_{21} & Y_{22} & Y_{23} & Y_{24} \\ \hline Y_{31} & Y_{32} & Y_{33} & Y_{34} \\ \hline Y_{41} & Y_{42} & Y_{43} & Y_{44} \end{array}\right]$$

Fig. 1. Matrix to be inverted

half of the matrix. The inversion rules are very simple and will be explained in detail for only one diagonal element. Let the diagonal element Y_{33} of Fig. 1 be selected for explanation. The rules are as follows:

1. All elements external to the row and column containing the diagonal element must be modified. These elements are modified one at a time.

For example, Y_{11} is modified to become

$$Y_{11}-\frac{Y_{13}Y_{31}}{Y_{33}} \quad (1)$$

The element Y_{14} is modified to become

$$Y_{14}-\frac{Y_{13}Y_{34}}{Y_{33}} \quad (2)$$

The element Y_{42} is modified to become

$$Y_{42}-\frac{Y_{32}Y_{43}}{Y_{33}} \quad (3)$$

The element Y_{44} is modified to become

$$Y_{44}-\frac{Y_{34}Y_{43}}{Y_{33}} \quad (4)$$

The other external elements are similarly modified.

2. The element Y_{33} is replaced by $-1/Y_{33}$. Each other element in the row and column common to Y_{33} is multiplied by $-1/Y_{33}$.

3. Rules 1 and 2 must be repeated for each main diagonal element. The resulting matrix will be minus the inverse of the original matrix. The operations may be carried out in any sequence. Note that symmetry is not a requirement when the entire matrix is used.

Adaptability to Computer

The method described was originally devised to invert matrices in the high-speed memory of a 16,000-word IBM (International Business Machine Corporation) *704* computer. Symmetrical matrices in complex numbers slightly larger than 100 by 100 can be inverted by this computer. In addition to the program and the matrix in triangular form, it is necessary to provide additional memory location for only one matrix element. For convenience in checking the inverse, space is provided for one row of the original matrix. Thus, the memory requirements and the numerical work required has been minimized.

The method is adaptable to the inversion of larger matrices by the use of tape. In this case, it is probably best to store each complete row of the matrix as a record on a binary tape. Thus it becomes possible to perform arithmetic operations on one row of the matrix at a time. Such a procedure limits the size of the matrix only by time requirements and by round-off error when this becomes a problem.

For very large matrices the method is adaptable to partitioning. The matrix may be partitioned so that square submatrices are formed along the main diagonal. The submatrices need not all be the same size. The submatrices along the diagonal may then be inverted and the complete inversion of the large matrix accomplished by carrying out matrix operations similar to those described for the individual elements.

Derivations

The method described was derived more from a knowledge of electric circuits than from a knowledge of mathematics. A normal job for the a-c network analyzer is to derive an equivalent circuit for a power system holding a smaller number of busses than actually exist on the power system. This is usually done by plugging the power system on the analyzer and connecting each bus to be held through a metering jack to a common bus. Thus, by opening one metering jack at a time and applying a voltage, the equivalent circuit may be determined from the currents that flow in the metering jacks. This procedure is the equivalent of Kron's reduction formula as described by the matrix equation:

$$Z_1-Z_2Z_4^{-1}Z_3 \quad (5)$$

In equation 5, Z_1, Z_2, Z_3, and Z_4 are submatrices resulting from partitioning a large matrix, where Z_1 is the upper left corner, Z_2 the upper right corner, Z_3 the lower left corner, and Z_4 the lower right corner. Z_1 and Z_4 must be square.

If in equation 5, Z_1 and Z_4 are made the same dimension and if $Z_1=0$, and if $Z_2=Z_3=I$ (the identity matrix), then the resulting expression becomes $-Z_4^{-1}$. Now, the same results as expressed in equation 5 can be obtained by eliminating one row and one column at a time. Thus, with the described restraints on Z_1, Z_2, Z_3, and Z_4, it is possible to place the newly calculated elements back in the Z_4 positions. Therefore, the memory space that would normally be required for Z_1, Z_2, and Z_3 is not needed. The simple rules just described are the result of observing the effect of this operation.

In partitioning a very large matrix to be inverted, observe that it may be possible to do so, in such a way that the off-diagonal submatrices contain only zeros. This, of course, will save considerable numerical work. In fact, it supplies some insight into Kron's method of diakoptics. For example, if the matrix to be inverted is an admittance matrix of a transmission system, the off-diagonal elements represent physical lines on the power system. Thus, if certain lines are simply omitted from the power system, the partitioned matrix reduces to compound diagonal form. Therefore, the compound diagonal elements are simply inverted to obtain the matrix inverse less the lines that were omitted. The omitted lines can be added by inverting a matrix whose dimensions are equal to the lines omitted. Subsequent matrix operations (not involving inversion) give the required inverse. Obviously, if too many lines must be left out of the original matrix the process of reinserting them may involve more work than the inversion of the original matrix. Usually diakoptics saves work when there are already many zeros in the system to be inverted.

Possible Extension of the Method

From the description it is apparent that the method cannot be used in its present form to invert a matrix that has all zeros along the main diagonal. Combinatorial topology supplies a possible means of circumventing this difficulty. For example, an arbitrary number is simply inserted for one of the zeros in the diagonal position. The matrix is then inverted and the inverse is modified to remove the arbitrarily inserted number. In mathematical operation, the modification is identical to switching a line in the power system impedance matrix. This procedure has been outlined in reference 1. The matrix modification (or line switching) requires 12 seconds on a 100-by-100 matrix. In electrical engineering terms, the operation is similar to placing a line in service while other work is done on the power system, and then removing the line from service.

Of course, it is possible that changing only one of the zero diagonal elements will not permit the method to invert the matrix. In this case it may be necessary to change arbitrarily more than one of the elements. Of course, it will be necessary to make as many modifications of the inverse as there were lines added to the original system.

This description does not intend to imply that extensive investigations have been carried out to avoid the difficulties that may arise in special cases.

Conclusions

The method described was devised for use with a 16,000-word IBM *704* computer using single precision arithmetic. The machine time required is a function of the number of zeros in the matrix. A 100-by-100 complex matrix inversion with no zeros required 24 minutes of computing time. A normal power system admittance matrix, 99 by 99, required 11 minutes to invert. The technique described has not been extensively used as an inversion method. Its equivalent as a part of several other programs developed by TVA has been used successfully to invert hundreds of matrices of varying sizes up to and including the maximum size that can be accommodated in high-speed memory. Present practice requires that each inverse be checked by multiplying the inverse by the original matrix. Usually this results in an identity matrix when rounded to the fifth or sixth significant figure, depending upon the particular matrix and the amount of computing involved. This method will usually invert a normal power system matrix faster than the multiplication check can be accomplished, if one matrix must be retained on tape because of memory limitations.

Discussion

Gordon K. Carter (General Electric Company, Schenectady, N. Y.): In this paper the authors have apparently attained the ultimate in minimum storage for direct inversion of a matrix, along with the maximum speed for such a process. The following comments are intended to be helpful by relating the procedure to the process of elimination of variables, which may be more familiar to some readers than Kron's reduction formula and the associated circuit manipulations. The elimination method has been illustrated[1] by a simple 3-variable numerical example which could be written more formally as follows:

$$\begin{aligned} A_{11}X_1+A_{12}X_2+A_{13}X_3&=Y_1+0+0\\ A_{21}X_1+A_{22}X_2+A_{23}X_3&=0+Y_2+0\\ A_{31}X_1+A_{32}X_2+A_{33}X_3&=0+0+Y_3 \end{aligned} \qquad (6)$$

The inversion process interchanges the forms of the two sides of these equations, so that (X_1,X_2,X_3) can be evaluated by simple multiplications and additions for given (Y_1,Y_2,Y_3), just as the reverse is true for these original equations. This can be done by eliminating X_1, say, from all but the first equation; then X_2, say, from all but the second; etc. Only one such elimination need be described, since the rest follow the same pattern of operations. For instance, to eliminate X_1 from all but the first equation:

1. Divide the first equation by A_{11}.

2. Multiply the resulting expression by A_{21} and subtract from the second equation; multiply by A_{31} and subtract from the third; etc.

3. At this point the expressions appear as follows:

$$\begin{aligned} X_1+&\frac{A_{12}}{A_{11}}X_2+\frac{A_{13}}{A_{11}}X_3=\frac{1}{A_{11}}Y_1+0+0\\ 0\ +&\left(A_{22}-A_{21}\frac{A_{12}}{A_{11}}\right)X_2+\left(A_{23}-A_{21}\frac{A_{13}}{A_{11}}\right)X_3=-\frac{A_{21}}{A_{11}}Y_1+Y_2+0\\ 0\ +&\left(A_{32}-A_{31}\frac{A_{12}}{A_{11}}\right)X_2+\left(A_{33}-A_{31}\frac{A_{13}}{A_{11}}\right)X_3=-\frac{A_{31}}{A_{11}}Y_1+0+Y_3 \end{aligned} \qquad (7)$$

In terms of digital computer operation, storage need be provided only for coefficients which are of an unknown, or variable, character from problem to problem. In expressions 1 and 2 there are no more of these than the number in the original matrix of A_{ij}. Consequently, if in expression 2 the coefficients of Y_1 are stored where the A_{i1} originally were, the storage requirements are at a minimum; but of course a record must be kept to ensure that the elimination ultimately takes place once and only once for each of the original matrix columns.

An embodiment of this procedure as a program for the IBM *650* computer recently came to our attention.[2] That particular program uses extra storage equivalent to one extra row of the matrix; it probably uses fewer operating instructions, but is less flexible, than the authors' method.

Comparison of the elimination procedure with that of Shipley and Coleman shows that the operations are nearly identical. The only material difference is in the appearance of negative signs in both the row and column of the pivotal term in the paper, whereas, in the straight elimination process, terms in the pivotal row carry a positive sign. In the end, this results in the development of the negative of the inverse matrix in the first case, the actual inverse in the second.

As the authors point out, the elimination can proceed in any order. For instance, at each stage the pivotal element can be chosen as the largest of those on the main diagonal which remain to be processed. From the more general point of view, however, it is not necessary to restrict the pivotal elements to the main diagonal. Any set could be used, so long as no two are chosen from the same row or the same column. From the standpoint of error control, for example, it might be desirable to choose for the pivotal element at any step the largest term in any part of the matrix not in conflict with the rule against duplicating rows and columns; the penalty would lie in the need for appropriately rearranging the rows and columns of the final matrix so that it is the proper inverse of the original one.

2. Minimum-Storage Matrix Inversion, Victor W. Bolie. *Zietschrift fuer Angewandte Mathematik und Mechanik*, Berlin, Germany, vol. 38, Sept.-Oct. 1958, pp. 369–72.

V. Converti (Arizona Public Service Company, Phoenix, Ariz.): The authors' intriguing new method of matrix inversion is adequate for the inversion of any matrix, in general, and welcome for the inversion of large power system matrices, in particular. The technique developed in the paper is of particular value because it is based on a direct method of inversion, thus avoiding inversion by iteration processes; and because the storage requirement for the input is reduced to the triangular form of the matrix. It therefore represents a significant contribution to the continued effort of increasing the speed of inversion over available general inversion methods, and of reducing input requirements of large power system matrices handled by digital computers.

The authors' method can be applied to the calculation of network equivalents by a modification of the general case. The mathematical operation for the general case is based on the application of rules 1 and 2 of the method to each element of the matrix for successive rows and columns. As outlined by the authors, rule 1 makes use of Kron's reduction formula, which operates on those elements external to the row and column selected, while rule 2 operates on the row and column selected.

Rule 1 is exactly what is needed when one row and one column are eliminated from the matrix. Therefore, restricting the operation to rule 1 only, one row and one column are eliminated each time the reduction formula is applied to all elements affected. By repeating the process on the reduced matrix by one, the next row and column can be eliminated, and so on. This operation corresponds to the familiar network reduction steps performed by hand.

Thus, to obtain driving point and transfer admittances representing an equivalent network for use in a stability study, only two steps are needed with the use of rule 1:

1. Formation of the self- and mutual-admittance matrix of the original network with the nodes to be retained preferably on the left-hand corner of the matrix for ease of reference. (This operation is common to any method.)

2. Application of rule 1 to eliminate all rows and columns containing those nodes to be eliminated.

In addition to the advantages indicated by the authors, of faster inversion and reduced storage requirement, the use of this modified method to calculate network equivalents makes available for the first time a step-by-step record of the network reduction process. This, in effect, would require the writing on the output, if so desired, of the reduced matrix after each node elimination representing the network at that particular stage of computation. The reduced matrix can be made available on tape for further processing, or as a starting point for changes in the network configuration.

H. W. Hale (Wayne State University, Detroit, Mich.) and **R. W. Goodrich** (University of New Hampshire, Durham, N. H.): That the general method has other useful applications may be shown by a description of the program we have developed for a different purpose, but which is similar to the authors's useful technique.

In a recent paper[1] we described a procedure for the digital solution of power flow problems that makes use of network equations of the form

$$\left\| \begin{matrix} I_1 \\ \vdots \\ I_J \\ \\ E_K \\ \vdots \\ E_N \end{matrix} \right\| = \left\| \begin{matrix} Y_{11} \ldots Y_{1J} & D_{1K} \ldots D_{1N} \\ \vdots \qquad \vdots & \vdots \qquad \vdots \\ Y_{J1} \ldots Y_{JJ} & D_{JK} \ldots D_{JN} \\ & \\ D_{K1} \ldots D_{KJ} & Z_{KK} \ldots Z_{KN} \\ \vdots \qquad \vdots & \vdots \qquad \vdots \\ D_{N1} \ldots D_{NJ} & Z_{NK} \ldots Z_{NN} \end{matrix} \right\| \left\| \begin{matrix} E_1 \\ \vdots \\ E_J \\ \\ I_K \\ \vdots \\ I_N \end{matrix} \right\| \tag{8}$$

where the Y's, D's, and Z's are admittances, dimensionless transfer ratios, and impedances respectively. An additional note is made that D_{KJ} is the negative of D_{JK}.

The determination of the elements of the coefficient matrix of equation 8 from either the impedance or admittance matrix is the purpose for which our program was developed. The basic ideas are illustrated by starting with the network equations in the form

$$\left\| \begin{matrix} I_1 \\ \vdots \\ I_K \\ \vdots \\ I_N \end{matrix} \right\| = \left\| \begin{matrix} Y_{11} \ldots Y_{1K} \ldots Y_{1N} \\ \vdots \qquad \vdots \qquad \vdots \\ Y_{K1} \ldots Y_{KK} \ldots Y_{KN} \\ \vdots \qquad \vdots \qquad \vdots \\ Y_{N1} \ldots Y_{NK} \ldots Y_{NN} \end{matrix} \right\| \left\| \begin{matrix} E_1 \\ \vdots \\ E_K \\ \vdots \\ E_N \end{matrix} \right\| \tag{9}$$

The matrixes of equation 2 may be compounded as shown and the positions of the variables I_K and E_K interchanged with the result that

$$\left\| \begin{matrix} I_1 \\ \cdot \\ \cdot \\ \cdot \\ E_K \\ \cdot \\ \cdot \\ \cdot \\ I_N \end{matrix} \right\| = \left\| \begin{matrix} Y_{11} - Y_{1K} \; Y_{KK}^{-1} \; Y_{K1} \ldots Y_{1K} \; Y_{KK}^{-1} \ldots Y_{1N} - Y_{1K} \; Y_{KK}^{-1} \; Y_{KN} \\ \cdot \qquad\qquad \cdot \qquad\qquad \cdot \\ \cdot \qquad\qquad \cdot \qquad\qquad \cdot \\ \cdot \qquad\qquad \cdot \qquad\qquad \cdot \\ -Y_{KK}^{-1} \; Y_{K1} \quad \ldots \quad Y_{KK}^{-1} \quad \ldots \quad -Y_{KK}^{-1} \; Y_{KN} \\ \cdot \qquad\qquad \cdot \qquad\qquad \cdot \\ \cdot \qquad\qquad \cdot \qquad\qquad \cdot \\ \cdot \qquad\qquad \cdot \qquad\qquad \cdot \\ Y_{N1} - Y_{NK} \; Y_{KK}^{-1} \; Y_{K1} \ldots Y_{NK} \; Y_{KK}^{-1} \ldots Y_{NN} - Y_{NK} \; Y_{KK}^{-1} \; Y_{KN} \end{matrix} \right\| \left\| \begin{matrix} E_1 \\ \cdot \\ \cdot \\ \cdot \\ I_K \\ \cdot \\ \cdot \\ \cdot \\ E_N \end{matrix} \right\| \tag{10}$$

The only difference in the coefficient matrix of equation 3 and that obtained by the application of steps 1 and 2 of the paper is in the algebraic signs of the elements in the Kth column. The method described in the paper has the effect of manipulating equation 2 into the form of equation 3 with the elements in the Kth column of the coefficient matrix multiplied by -1 and with I_K replaced by $-I_K$.

The positions of another pair of variables can now be interchanged in an identical manner and this process continued step by step until the desired equation 1 is determined. It is obvious that the impedance matrix could also be used as a basis for beginning the computations.

Fig. 2 shows a flow diagram of a program that we have been using to accomplish these computations. The following notation applies to this flow diagram.

K = terminal pair where variables are being interchanged
J, M = indexes of terminal pairs
N = number of terminal pairs
A = index of number of times major loop has been traversed or is in process of being traversed
K_A = value of K corresponding to a particular value of A
B_{JM} = number in position JM at start of major loop for a given value of A
B_{JM}' = number in position JM at completion of major loop for a given value of A

The program described by Fig. 2 has several features worthy of mention:

1. All of the elements of the matrix are retained. The discrepancies between corresponding off-diagonal values are useful as a partial indication of the accumulated round-off error, although other tests are applied to the results to give a more qualitative indication. The program can be easily modified to exploit the symmetries of the matrix.

2. Intermediate results are available at the completion of any cycle of the major loop.

3. The order in which terminal-pairs are treated can be controlled by means of the correspondence established between values of A and K_A. This can produce certain computational advantages and is also useful for producing desired intermediate results.

4. When A_M is set equal to N, the result is a complete inversion of the matrix.

The similarities and differences between the program described here and that described in the paper are obvious. The limitations described in the paper also apply here.

1. DIGITAL COMPUTATION OF POWER FLOW—SOME NEW ASPECTS, H. W. Hale, R. W. Goodrich. *AIEE Transactions*, pt. III (*Power Apparatus and Systems*), vol. 78, 1959 (*Paper no. 59-224*).

W. C. Marble (Philadelphia Electric Company, Philadelphia, Pa.): The authors present a thought-provoking paper: their method of matrix inversion permits a reduction in storabe requirements and calculating time which will be valuable for digital computation. One wishes, however, that they had been less laconic in their description of the method. My first attempt to apply the method produced a technique which successfully inverted strongly diagonal matrices, but failed to invert a simple, well-conditioned matrix with a weak diagonal. This resulted from a misinterpretation of the rules given in the paper. To prevent others from being similarly mislead, a fuller description of the authors' method would be helpful.

The method presented permits one to take advantage of symmetry throughout the inversion process; it also illustrates a fa-

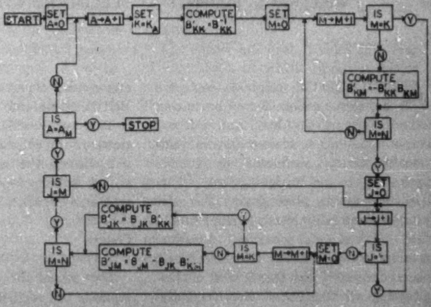

Fig. 2. Flow diagram for interchanging variables

cility in comprehending power system operation in mathematical terms, and vice versa, a characteristic of Mr. Shipley's work which should be admired, and imitated.

R. Bruce Shipley and Dorothy Coleman: The authors wish to express sincere appreciation for the prepared comments. We apologize to Mr. Carter for not having referred to his excellent paper (see reference 1 of the Carter discussion). It is true that the arithmetic is similar if the entire matrix is to be used. However, the use of minus on the pivotal term causes a symmetrical matrix to remain symmetrical throughout all the operations and reduces the memory requirements as well as the arithmetic by approximately one half. This seemingly trivial difference reduces the cost of matrix inversion by one half and doubles the number of matrix elements that can be accommodated in a given digital memory size. A 16,000-word memory will accommodate a symmetrical matrix slightly larger than 100 by 100 in complex numbers, when stored in triangular form. If the complete matrix is to be stored, a 32,000-word machine would be required, and this increases the monthly rental by almost $5,000. Mr. Carter's suggestion of always processing the largest diagonal element first will improve accuracy. The use of the largest element in the matrix as a pivotal element should be expected to improve accuracy, but if it is placed in the diagonal position by interchanging rows, the matrix does not remain symmetrical and the advantage of using only half the matrix is lost.

We agree with Mr. Converti that the direct inversion method is faster than the iterative method when the matrix can be stored in high-speed memory. We are not sure that it will be faster than Mr. Converti's iterative method[1] if the matrix must be stored on tape. Neither are we sure that the direct method is superior to the iterative method if roundoff error becomes a serious problem. To date we have had no serious problem with roundoff errors in inverting power system matrices. We have used the equivalent circuit method suggested by Mr. Converti for about one year and find it very satisfactory from the standpoint of speed and accuracy. It might be noted that equivalent circuits can be derived from the impedance matrix as well as from the admittance matrix. This requires the inversion of only that part of the impedance matrix representing the busses to be held, while the remaining portion of the matrix is simply ignored. The reference bus must be one of the points held. We employ a subroutine that interchanges the reference bus with any other bus in the system, enabling us to hold any combination of busses represented by the impedance matrix. The work done by this subroutine would require about 12 seconds for a 100 by 100 complex matrix on an IBM *704*.

The Hale-Goodrich idea of solving load flow with certain sets of currents as variables and other sets of voltages as variables was possibly first applied by Shipley and Hochdorf.[2] The exact technique of Hale and Goodrich was not used because the additional matrix product RI (where R is the real component of the impedance matrix) was needed. It is not apparent that RI is available from the Hale-Goodrich method without additional computations. It is apparent that the subject inversion method will permit a larger power system load flow to be used since it preserves symmetry. Further, it is more convenient since the sets of variables can be chosen at random in the matrix equation. It will be necessary to change the signs of the variables as they are transferred back and forth across the equality sign.

In reply to Mr. Marble's comments, the following numerical example may be used to demonstrate the individual steps as applied to a complete matrix:

Invert the matrix:

$$\begin{matrix} -23 & 11 & 1 \\ 11 & -3 & -2 \\ 1 & -2 & 1 \end{matrix}$$

Applying rules 1 and 2 to the Y_{33} element gives

$$\begin{matrix} -24 & 13 & -1 \\ 13 & -7 & 2 \\ -1 & 2 & -1 \end{matrix}$$

Next, apply rules 1 and 2 to the $Y_{22}(-7)$ element of the new matrix to give

$$\begin{matrix} 0.142833 & 1.857141 & 2.714282 \\ 1.857141 & 0.142857 & 0.285714 \\ 2.714282 & 0.285714 & -0.428572 \end{matrix}$$

Complete the procedure by applying rules 1 and 2 to the Y_{11} (0.142833) element to give minus the inverse

$$\begin{matrix} -7.001183 & -13.002183 & -19.003185 \\ -13.002183 & -24.004030 & -35.005880 \\ -19.003185 & -35.005880 & -52.008575 \end{matrix}$$

This matrix was taken from the book by Hartree,[3] who gives the inverse as

$$\begin{matrix} 7 & 13 & 19 \\ 13 & 24 & 35 \\ 19 & 35 & 52 \end{matrix}$$

A New Approach to Training Telephone Engineers

WILLIAM C. BURNETT
MEMBER AIEE

LEONARD C. ADAMS
ASSOCIATE MEMBER AIEE

A PICTURE OF telephone engineers living in a college dormitory, eating in a college dining hall, and walking across a campus to classes on communications theory conducted by college professors is an intriguing one. This has been taking place during the past year in South Carolina. It is part of a new method of providing technical training to experienced telephone engineers developed by the School of Engineering of Clemson College and the engineering department of the Southern Bell Telepone and Telegraph Company.

This paper will tell how this revolutionary form of training came into being, will discuss the manner in which the school is being operated, and will present an evaluation of the early results.

Origin

This school had its beginning in two separate but related events. The Southern Bell Telephone and Telegraph Company recognized that it needed a survey of the needs for training in its engineering department. To this end a study was made during the summer of 1956 by a college professor, whose assignment was to explore the needs for training telephone company engineers and the training program as it existed, and to make recommendations for a comprehensive training program. Frequent contact was made with the training people of the engineering department, and trips were

Paper 58-1152, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958; the Winter General Meeting, New York, N. Y., February 1–6, 1959; and the Southeast and South Central Meeting, Atlanta, Ga., April 8–10, 1959. Manuscript submitted June 16, 1958; made available for printing June 24, 1958.

WILLIAM C. BURNETT is with the Southern Bell Telephone and Telegraph Company, Birmingham, Ala. LEONARD C. ADAMS is with Clemson College, Clemson, S. C.

made into the operating areas to interview engineers at all levels. The study revealed that the company had a shortage of engineers who might be available as instructors in telephone training courses. As a result, one suggestion was that it might be possible to make use of professional instruction, that is, teachers from college engineering departments.

During the same summer, the transmission engineers of the company met to discuss their needs, and found that one of their greatest was specialized training in telephone transmission engineering for their people. When this was discussed with the personnel of the training section, it was pointed out that prior commitments would make it impossible for a transmission engineering school to be conducted before 1958. The transmission engineers were completely dissatisfied with this situation. The need for early training was urgent.

There were two reasons for this urgency. It had been many years since the company had conducted any sort of transmission school, and during this time many new people had come into the transmission sections. But of greater importance was the expected effect of the vast changes that are taking place in the telephone communications industry. In very recent years the industry has begun to provide a multitude of new types and kinds of services that people and business want and need in this rapidly changing world. In the past the Bell Telephone System has generally followed a system of engineering that begins in the Bell Telephone Laboratories, where basic research is done. General application engineering is a major activity of the operation and engineering department of the American Telephone & Telegraph Company. It is here that Bell System engineering practices are prepared. These are distributed to all the operating companies which, in turn, use them in their local application engineering. When special problems arose, or new and different communications services were proposed, these matters were frequently referred by local area engineers to their headquarters and often to the operations and engineering department in New York City.

Recently the Southern Bell Company decentralized practically all engineering to the nine state areas, which now develop solutions to the special problems and design facilities to care for new and different services. As a consequence the work of the transmission engineers in the state areas has become much more complex and carries far more responsibility. Therefore, their staffs require more thorough training than before.

Another consideration was the nature of the training which the transmission engineers desired for their staffs. From the late 1920's through the 1940's the Southern Bell transmission schools had combined theory with application, making use of equipment and circuits that were in common use throughout the Bell System. Students came from both engineering and operating departments, and the engineering emphasis was on application rather than fundamental principles. Recognizing that basic knowledge is of greater value to the design engineer than is application knowledge, the transmission engineers wanted training to stress the underlying theories of communication circuit design. It was felt that not only would the basic theory be remembered better and longer, but also it would better equip an engineer to tackle and solve the problems of providing new and different communications services.

Further discussion by the transmission and training groups resulted in a proposal to combine the need for early training with a suggestion that college instructors present courses for a telephone school. Since much of the training desired would be basic and of a theoretical nature, it was clear that professional instructors could do this teaching better than telephone engineers.

Overtures were made to Clemson College in South Carolina, and a favorable response was received. Then the transmission engineers established a steering committee to organize the broad aspects of the training course desired, and an outline was presented to the college. Details were developed in joint discussions between the college staff and telephone company engineers, and both groups became enthusiastic about the possibilities of operating a school of the type desired.

The college regards this program of instruction as an industrially supported engineering extension service. Clemson has, for many years, conducted short-courses for agricultural groups. Thus the administration readily accepted the program. This was an opportunity to serve southern industry and, at the same time, to bring about an association with benefits accruing to both company and college. Final acceptance of the idea rested with the electrical engineering faculty. This group adopted the program in a formal meeting without a dissenting vote. Five members of the staff requested a part in the project and others offered to serve if needed.

Advantages of Campus-Type School

A major advantage of the Clemson plan is the use of professional teaching. It is logical that those persons experienced in teaching will do a better job than those whose life work is applied engineering. The ability of a man to design or to solve engineering problems does not necessarily equip him to explain them. Thus, many excellent engineers are poor teachers. Furthermore, it is felt that company instructors could not cover in the allotted time as much ground as do the professors; the company instructors wander off the highway of theory onto the interesting byways of telephone application and personal experiences.

Another major advantage comes from having students in an environment that is conducive to study and learning. Thus, housing telephone students in a domitory, feeding them in a college dining hall, and assembling them in regular classrooms provide atmosphere and climate that are in very favorable contrast to the former arrangement of holding schools in city hotels, which are inherently surrounded by interesting but time-consuming diversions.

Further, there accrues a net saving in engineering manpower because professional teachers can teach fundamentals with less added work than company instructors.

Course of Instruction

In August 1956, the company's transmission engineers chose a steering committee composed of five transmission engineers with the engineering training supervisor as an ex officio member.

From the beginning it was intended that this school would be basically fundamental. As stated previously, it was believed that in the long run engineers would obtain the most benefit from training in fundamentals. Consequently theory, rather than application, has been emphasized.

The school has been divided into four courses, each of which covers a major subject or grouping of subjects. The first course ran 3 weeks; each of the other three are 2 weeks in length. Each course is repeated as many times as needed to accommodate the number of students to be sent. The company regards this arrangement as superior to previous similar schools which the student attended continuously for approximately 8 weeks.

In the first place, this plan promotes efficiency in that once the teaching staff has prepared work for a course, it can present the material every 2, 3, or 4 weeks with a minimum amount of time for review of the lesson plan. Second, the absence of an engineer from his desk for periods of 2 weeks each is far less disrupting to production than is a single absence of 9 weeks. Also, most of the men are much happier if they are not away from home for extended periods. Finally, the divided plan provides desirable flexibility in scheduling the students for those courses which they most need. Some men will take all courses while others may require only one.

The first course, 3 weeks, covers basic transmission theory, including acoustics, transmission lines, and active elements. The second course, 2 weeks, deals with the theory of low-frequency and voice-frequency induction, protection, and corrosion. In the third course, also 2 weeks, the subjects are crosstalk and carrier transmission. The final 2-week course embraces the fundamentals of radio. An outline of the subjects is given in the Appendix.

It was mentioned previously that this school is charged with teaching the basic theory of telephone communications. The application training which should follow has been made a responsibility of the nine state areas. The depth and breadth of this application training will vary according to the needs of the engineers in each area.

Using material furnished by transmission engineers, the professors prepared their own lectures and lesson plans. Quite naturally the nature of material furnished by the company varied with the subject. For instance, the subjects of acoustics, transmission lines, and active networks are generally familiar to an electrical engineering teaching staff. The steering committee and representatives of the college developed the course outline. The individual professors in the electrical engineering department then completed the preparation.

Without recourse to telephone material or reference to telephone company problems in this field, a professor in the chemistry department prepared and taught an excellent course on the theory of corrosion. On the other hand, telephone engineers who are specialists in these subjects prepared detailed lectures for the course on crosstalk theory, transposition theory, and transposition design.

Because of our firm conviction that the quality of teaching by professionals is very much the better, to the maximum practical extent teaching is being done by members of the college faculty. However, where the subject is completely unfamiliar to the faculty, telephone engineers who are considered to be suitable teachers take over the assignment. Most theory is taken by the college faculty, while those applicaton subjects that are peculiar to the communications business become the responsibility of telephone engineers. About 85% of the classroom hours are taught by the professors.

The amount of time spent in classroom work is based upon the schedule of a typical undergraduate engineering student. This amounts to about 24 contact hours per week. Although the volume of subject matter covered is considerable, it is not deemed practical from any point of view to hold the students in formal session for more than 20 to 24 hours each week. Furthermore, homework reading and problem assignments require from 1 to 2 hours out-of-class study per contact hour.

A course consists of several independent subjects each of which is assigned to a different teacher. Thus, the overload on any one staff member is held to a safe minimum. Once the subject breakdown is made, scheduling the program is no great problem. Participants indicate the hours available and their preference of hours for subject offerings. As a result, the schedule literally adjusts itself to an even spread throughout the week.

Most of the textbooks being used are standard technical books. Some are provided on the basis of one for each student, whereas others are made available in several copies for reference use. The texts have been supplemented by Bell System Practices, Bell Telephone Monographs, and other suitable material.

Usually the teacher furnishes to the students handouts consisting of lesson plans and other pertinent material. These promote efficiency in teaching and learning, and provide references for the engineers after they return to their jobs.

In the References is a list of the textbooks which are being used in the school, not including The Bell System material. The steering committee has recommended that the transmission sections in the state areas build up their technical libraries with many of these texts.

In the interest of conserving time, no laboratory work is included in the course but demonstrations are used to emphasize certain theory.

The faculty instructors feel that it is not fair either to the short-course student or to the college to grade the men taking the course. They are not on the campus long enough for this. However, the company wishes to know which of its engineers excel in fundamental theory, so two grades are given. All participants receive a grade of S (satisfactory) except a small percentage who do exceptionally good work. These receive a grade of E (excellent). The company is furnished no further grading information. Grades are based upon homework papers and a series of quizzes given during the course.

Students

The subject material has been pitched at the college senior and graduate level. Therefore the general student qualification is that he should be an electrical engineering graduate or possess equivalent theoretical background. Equivalence could be attained by a college or high school graduate who had considerable technical experience, informal education, and training within the company.

The original intent was to provide advanced training for transmission engineers and for engineers who were good prospects for transmission work. Then it was decided to open the door to transmission maintenance personnel from the plant department.

No tests are given to prospective students. Rather, they are chosen by the state areas on the basis of their formal education, company training, telephone experience, present duties, and ability to absorb high-level training. We believe that generally good choices have been made.

Several weeks prior to his attendance at a semester of schooling, each student is sent a textbook and other material for advance study. This enables him to determine what reviewing he needs to do and to acquire some familiarity with the text. In turn, this promotes efficiency in learning while he is at Clemson.

Mechanics

Telephone Company students are housed in a dormitory that has always been used for short-course groups. During the last 5 years, Clemson has erected new housing which has been more than adequate for her growing body of about 4,000 resident students. Thus the housing officer has made a block of 25 rooms available to the telephone school for its duration, or until such time as they are needed for the student body.

Clemson students eat, family style, in a single tremendous dining hall. Normally, a boarding student pays for room and board at the beginning of the semester and is admitted to the dining room upon identification by card. Short-course students are accommodated in the same way. The cost per student is slightly greater to allow for maid and linen service, a service not available to the undergraduate resident.

Evaluation

Student reaction must be considered in the light of the intent of the school, which is to provide high-level training in the basic theories of communications circuits and components. Many of the students have come away from a 2-week or a 3-week session feeling that they had been swept up onto a cloud and left there, unable to pierce the fogs and mists of theory and see the everyday job back on earth. This is neither an unexpected development nor one that causes us concern. The planners of the Clemson school wanted major emphasis on basic theory and intended that the state areas would carry out suitable application training. As an example of this, the Alabama area will hold, upon the completion of the current semester of the Clemson school, a 3-day seminar in which applications will be discussed. This seminar will be attended by all of the Alabama engineers who have been enrolled in the Clemson program. By this means the training of engineers will be made more nearly complete.

After a good look at the Southern Bell curriculum and schedule at its Clemson school, and with the usual engineering curriculum in his mind, one professor observed, "It looks like Southern Bell's intent is to whet the appetite of its students." He was contrasting the very rapid coverage in the telephone course with the thorough subject exploration and exposition that is typical of college courses. Having in mind the practical aspects of time limitations and the expected high quality of students, the steering committee planned a course of study that covered a great deal of ground quickly. We hope that we are not wrong in expecting that this communications training will stir up in each man such great interest that he will turn to a deeper home study of many of the subjects he encountered at Clemson. Certainly, an engineer who wishes to grow and develop and succeed will feel strongly that he needs to exert off-the-job effort to further his own development. There is, of course, opportunity to sandwich into the day-by-day job reading and study of technical material, but the man who is sincerely ambitious will realize that 8:30 to 5 efforts are not enough.

We expect that engineers who have had this training will have been equipped to get for themselves the most out of the technical information normally available for their use. And when new problems arise, problems that have not been anticipated or problems concerning new and different communications' services, the transmission engineers will have the basic knowledge to solve these problems. This is vastly important in the day of decentralization of telephone engineering and of a host of new and different services wanted and offered.

Highly important is the fact that this program is bringing about a new and closer relationship between education and industry. Formerly, industry has been considered to be interested only in profit, and the college to be interested only in courses in theory. The Clemson venture shows that this need not be so, for participation in this joint activity has developed a mutual interest, and a realization that both education and industry can benefit from working together.

Conclusion

When in 1956 the Southern Bell Telephone Company recognized the great need for technical training for its transmission engineers, it sought ways of providing this training. Full study of the problem developed a firm conclusion that basic training in theory and principles would be of greater value and more enduring than study of systems and applications.

When prior commitment of the engineering department's training staff indicated a serious delay in starting the needed training, inquiry located a state college that was interested in conducting courses of study on its own campus.

The development of a working arrangement with Clemson College was a most happy solution in that classes could begin soon, the teaching of basic theories could be admirably done by college professors, professional teachers can teach better than engineers, and the holding of classes on a campus would provide a climate highly conducive to learning.

By these means we are providing training that should enable our transmission engineers to think through unusual circumstances not covered in our Bell System Practices.

Appendix. Outline of School

Course I. (3 weeks)

A. Acoustics
   1. Sound
   2. Acoustical engineering and noise
   3. Information theory

B. Transmission lines
   1. Network theory, passive networks
   2. Electric wave filters
   3. Transmission line theory

C. Active elements
   1. Vacuum tubes
   2. Transistors
   3. Gain devices

Course II. (2 weeks)

A. Noise-frequency induction
   1. Fundamentals, noise sources, components
   2. Influence, harmonics, measurements
   3. Coupling and shielding
   4. Susceptiveness, investigations, surveys

B. Selective devices
   1. Theory, shunts, capacitors
   2. Propagation of harmonics

C. Low-frequency induction
   1. Sources
   2. Symmetrical components
   3. Power system faults
   4. Coupling factors
   5. Shielding

D. Protection
   1. Lightning
   2. Telephone plant
   3. Protective measures

E. Corrosion
   1. Theory

Course III. (2 weeks)

A. Crosstalk
   1. Theory
   2. Types of crosstalk
   3. Toll cable crosstalk
   4. Number splicing
   5. Exchange cable crosstalk
   6. Open wire crosstalk
   7. Carrier system co-ordination

B. Carrier transmission
   1. History, why modulate
   2. Kinds of modulation
   3. Sampling principle
   4. Quantization, code transmission, multiplexing
   5. Amplitude modulation
   6. Frequency modulation
   7. Pulse modulation
   8. Oscillators
   9. Linear amplifiers
   10. Filters
   11. Compandors
   12. Noise
   13. Systems
   14. Co-ordination of systems
   15. A look into the future

Course IV. (2 weeks)

A. Radio
   1. Modulation
   2. Oscillators
   3. Amplifiers
   4. Discriminators
   5. Limiters
   6. Waveguides, coaxial transmission lines
   7. Antennae
   8. Wave propagation
   9. Noise
   10. Air/ground
   11. Tropospheric or scatter

B. Theory of probability

Discussion

Ellis F. King (University of California, Los Angeles, Calif): The authors' reference to emphasis on "underlying theories of communication circuit design" is noted with interest. This is in contrast to an "appreciation" course (to employ the usual telephone terminology), an experience roughly correspounding to a "survey" course as the term is used in academic circles.

Appreciation courses are frequently characterized by their concentration within a few days, a relatively large number of hours per day, no outside assignments or study time, and the lack of any real increase in the student's ability to apply fundamental principles to the solution of engineering problems. Properly presented, they do provide an improved conversational knowledge of the "state of the art" and tend to promote better understanding of general company operations on an interdivisional and interdepartmental basis. Clearly, these results have merit. No apology need be made for such courses if company objectives are consistent with the limitations of such an educational experience.

In contrast, so-called theoretical courses emphasize principles rather than techniques, concepts rather than precepts, and ideas rather than hardware. Competently administered, they provide the framework of technical competence for performance at a professional engineeering level. There is rather general agreement that the anatomy of such courses should include substantial outside study time, problem assignments, and examination procedures.

It is most important in any industrial schooling that management distinguish between these fundamentally different sets of objectives and provide the proper educational format for the desired results.

Mr. Burnett and Mr. Adams have reported teaching procedures which, within the time limitations extant, appear admirably consistent with their stated objectives.

Further comment on two aspects of the paper seem in order.

1. The *a priori* assumption of satisfactory or excellent performance.
2. The designation of the program as a "training" experience.

It is conceivable that personnel might participate in such a program with performance which would cause supervision to question the advisability of continuation and/or participation in possible future courses based on the earlier work. We suggest a third category; persons for whom further consideration may be desirable in the form of consultations between the individual and his supervision. It is felt that such a procedure offers the possibility of improved communication in relating employee development to long-range company and employee interests, as well as better information for future selections. Details may be handled in a manner calculated to avoid embarrassment on the part of anyone concerned.

Finally, we would greatly prefer that such programs as the authors describe be designated as education rather than training. To many, and particularly to the academically oriented, training is associated with enhancement of ability at the craft and technician level basic theory, and how to perform in a particular job classification, are two different matters. Less confusion, both with higher management internally and the profession externally, would accompany this suggested exercise in semantics.

W. J. Miller (University of Alabama, University, Ala.): The sponsors of this educational program are to be congratulated on their ability to recognize that tailors are superior to hatters in making a coat. In other words, they have seen that proper teaching of principles and theories requires experienced teachers, and cannot be done effectively by practicing engineers.

They have also demonstrated an understanding that an engineering teacher rarely knows applications and practice sufficiently well to present such matters effectively.

This understanding and use of basic facts makes this program more promising than the usual short course presented to upgrade personnel.

There is usually some confusion in the use of the terms education and training. Since this course was not given to produce proficiency in the use of some new device or method, it appears to be a program in education as contrasted with training.

Since all individuals taking this course have backgrounds of Bachelor's level in electrical engineering, the material presented in this course is partly "refresher" and partly post-graduate in nature. Thus, this program appears to be, to a certain extent, following the pattern of the so-called post-graduate courses of the medical profession. This may indicate that the engineering profession is coming of age and an educational plan of this type is to be highly commended. It may become a pattern for professional improvement in other industries.

Analysis and Design of a Transistor Linear-Delay Circuit

R. P. NANAVATI
NONMEMBER AIEE

Synopsis: In this paper an analysis is presented of the emitter-coupled linear-time-delay circuit as well as a systematic design procedure which starts with a practical set of specifications. Some important fundamental limitations on the operation and design of the circuit are also presented. Experimental data are included to give an idea of the range of validity of the theory. A range of the ratio of maximum-to-minimum pulse width as high as several hundred has been obtained as compared with 10 or 20 obtainable from a similar vacuum-tube circuit. A ratio in excess of 30 was obtained with a deviation from linearity of less than 3%. Stages of this circuit have been successfully operated in cascade.

FIGURE 1 shows the delay circuit chosen from among many single-shot multivibrators. It might be noticed that the normal coupling from the collector of T_2 to the base of T_1 found in other monostable circuits is missing. For this reason the base of T_1 is an ideal place to trigger the circuit, and the collector of T_2 is an ideal place from which to obtain the output signal. The most important reason for the choice of this circuit is that its output pulse duration turns out to be an accurately linear function of the base voltage of T_1.

Considering the circuit performance as piecewise linear and the transistor to be represented as a dependent current generator, and neglecting the voltage drop between the emitter and base of a conducting transistor, it can be shown quite readily that the output pulse width is given by

$$t_0 = T\ln\left(1-\frac{V_{e0}}{E_{cc}}\right) + T\ln\left(1+\frac{\beta_1 R_1 V_{b11}}{(R_8+\beta_1 R_7)(E_{cc}-V_{e0})}\right) \quad (1)$$

where the notation for V's is as follows: The first subscript denotes at which terminal (i.e., emitter, base, or collector) the voltage is measured; the second subscript denotes that the voltage in question is measured on T_1 if the subscript is 1 and T_2 if the subscript is 2. The third subscript denotes the voltage before trigger is applied if the subscript is 0, and after the trigger if the subscript is 1. Because the emitters of T_1 and T_2 are at the same potential, their voltage is simply denoted by V_{e0}, V_{e1}.

In deriving equation 1 it has been assumed that

$$\frac{\beta_1 R_7 V_{b11}}{(R_1+\beta_1 R_7)E_{cc}} \ll 1$$

which is found to be true for most practical values obtained. Equation 1 can be approximated by

$$t_0 = T\ln\left(1-\frac{V_{e0}}{E_{cc}}\right) + T\frac{\beta_1 R_1 V_{b11}}{(R_8+\beta_1 R_7)(E_{cc}-V_{e0})} \quad (2)$$

and

$$T = R_6 C \quad (3)$$

if the higher order terms in the expansion of the logarithmic term are negligible as compared with the ones in equation 2. For most practical parameter values this is normally true. Under these conditions the output pulse width is seen to be a linear function of the input voltage. In addition, it should be noticed that if

$$R_8 >> \frac{R_4 R_5}{R_5+R_4} \quad (4)$$

then V_{b11} can be conveniently replaced by V_{b10} in equation 2 so that the output pulse width can be expressed wholly in terms of quiescent quantities. In the interest of linearity the foregoing inequality is made to satisfy.

Establishing a Limit on the Minimum Pulse Width Obtainable

Even though one of the advantages of the circuit of Fig. 1 is the linearity of performance, one of the important figures of merit is the ratio of the maximum-to-minimum output pulse widths. The circuit performance is not linear over the entire range from maximum-to-minimum obtainable pulse widths. Just the same, by appropriately calibrating the input potentiometer the circuit can be operated over a considerable range of output pulse widths.

Fig. 2 shows the base and collector waveforms of T_1 and T_2. In Fig. 2(C) V_{b2c0} stands for the base voltage that just cuts off base current to T_2. A careful study of the waveforms indicates that the following is true.

$$t_{0\,\mathrm{min}} \geq t_{d2}+t_{r2}+t_{s2} \quad (5)$$

Another fundamental limit which is obtained from the waveforms is the delay in the formation of output pulse width which is given by

$$t_{\mathrm{delay}} = t_{r1\,\mathrm{off}}+t_{s1}+t_{s2} \leq t_{r1}+t_{s1}+t_{s2} \quad (6)$$

Equations 5 and 6 are absolute limits. The rise, t_r, saturation, t_s, and decay, t_d, times for the transistor themselves have been worked out by Ebers and Moll[1,2] and more recently by Easley[3] taking into account the collector capacitance and load resistance. The decay time has been discussed in detail in a recent paper.[4]

Maximum Trigger Rate Considerations

It is possible to solve (through a straightforward though tedious algebra) for the frequency at which the real part of the impedance that the capacitance c in Fig. 1 sees ceases to be negative. This frequency has a range depending on the value of the external circuit components and is given by equation 7.

Paper 59-563, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Empire District Meeting, Syracuse, N. Y., April 29–May 1, 1959. Manuscript submitted March 6, 1958; made available for printing February 19, 1959.

R. P. NANAVATI is with Syracuse University, Syracuse, N. Y.

This paper presents the results of one phase of research sponsored by Rome Air Development Center under Contract no. *AF 30(602)-1626.*

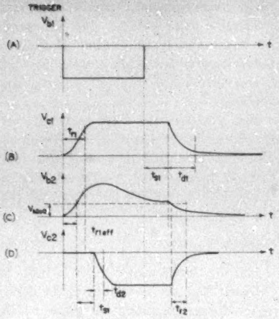

Fig. 2. Waveforms at different points in the circuit of Fig. 3

$$\omega_\beta \sqrt{1+\frac{\beta_0}{\alpha_0}} > \omega_{\max} > \omega_\beta \sqrt{1+\frac{\beta_0 R_7}{\alpha_0 R_1}} \qquad (7)$$

Equation 5 also puts a limit on the maximum trigger rate. Thus the maximum trigger rate is given by

$$f_{\max} = \min\left[f_\beta \sqrt{1+\frac{\beta_0}{\alpha_0}}, \frac{1}{t_{d2}+t_{r2}+t_{02}} \right] \qquad (8)$$

Design Procedure

The problem is to design the monostable circuit subject to the following specifications:

1. A range of available E_{cc}.
2. Maximum expected noise (spurious signals) E_n.
3. Minimum signal voltage available E_s.
4. Minimum output voltage required V_{omn}.
5. T_2 and, if possible, T_1 should not saturate.
6. Characteristics of the transistors used are available.
7. Maximum desirable output pulse duration $t_{0\,\max}$.

(In items 2 and 3 E_n and E_s are peak values of the voltages.)

The synthesis procedure should yield the following.

1. The values of R_1, R_2, R_4, R_5, R_6, R_7, R_8, C.
2. The required characteristics of the diode used.
3. The range of linearity.
4. The maximum ratio of maximum-to-minimum pulse widths.

The following are the steps taken to determine the foregoing quantities:

1. Choose the highest available E_{cc} consistent with the transistor ratings. This gives the best linearity, all other things being equal.

2. Choose a reasonable value of I_2 keeping in mind the fact that $I_2 > I_1$ (where I_2 and I_1 are the emitter currents of T_2 and T_1 respectively, and the α and β for both transistors are assumed identical). This means that the value of I_2 should not be very low, otherwise an unreasonable value of I_1 will have to be chosen.

3. Then choose

$$R_2 \geq V_{omn}$$

(This meets the output requirements.)

4. Choose

$$I_2 R_6 > \beta R_2$$

(This ensures the prevention of saturation of T_2.)

5. Choose

$$R_7 = \alpha \frac{E_{cc}}{I_2} - \frac{R_6}{\beta}$$

This is the analytical derivation of R_7 assuming the transistor characteristics to be piecewise linear.

A more realistic calculation of R_7 may be done graphically in the following way using the transistor characteristics furnished by the manufacturer together with the following equation:

$$R_7 = \frac{\alpha}{I_2}(E_{cc} - I_{b2} R_6)$$

Having located a desired operating point one reads off I_{b2} and I_2 directly from the transistor characteristics. Then having calculated R_7 from the foregoing equation one draws the load line of slope

$$-\frac{1}{R_7+R_2}$$

If the load line does not pass through the desired operating point, one chooses another point and goes through the cycle again until a decent operating point is arrived at. No more than three trips should be necessary.

Table I. Parameter Values Used in the Experimental Circuit

Resistors, Kilohms	Transistors*	Voltage	Capacitors	Diode
$R_1 = 18$	T_1	$E_{CC} = 10$ volts	$c = 0.01$ microfarad	$R_F = 200$ ohms
$R_2 = 6.8$	T_2			$R_B = 500$ kilohms
$R_4 + R_5 = 200$				
$R_6 = 270$				
$R_7 = 2.2$				
$R_8 = 270$				

* General Electric type *2N123*.

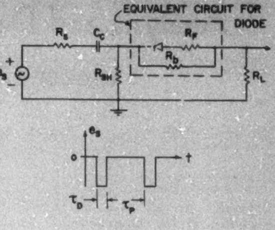

Fig. 3. A typical coupling circuit feeding a load R_L

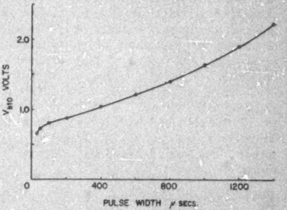

Fig. 4. Linearity data

$E_{cc} = -10$ volts

6. The choice of R_7 sets limits on V_{b10} as follows:

$$|E_s| \geq -|V_{b10}| + |I_2 R_7| \geq |E_n|$$

$$|V_{b10\,\min}| \geq |I_2 R_7| - |E_s|$$

$$|V_{b10\,\max}| \leq |I_2 R_7| - |E_n|$$

Observe that $|E_s| > |E_n|$.

7. Thus the range of voltages which the potentiometer must accomodate is

$$|V_{b10\,\min}| = |I_2 R_7| - |E_s|$$

$$|V_{b10\,\max}| = |I_2 R_7| - |E_n|$$

8. Choose

$$|I_1| < \left| \frac{V_{b10\,\min}}{R_7} \right|$$

where it has been assumed that

$$V_{b10\,\min} = V_{b11\,\min}$$

(This condition ensures the conduction of T_1 during the pulsing cycle.)

9. Choose

Table II. Comparison of Measured and Theoretically Calculated Values

Measured, Microseconds	Calculated, Microseconds	% Error
50	52.7	−5.12
100	105	−4.75
250	240	+4.17
300	281	+6.78

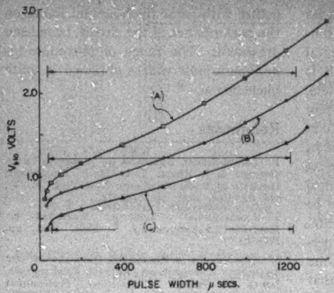

Fig. 5. Linearity data of the output stage of two cascaded stages

A—Ratio = 31, deviation <3%, jitter <0.5%, $E_{cc} = -13$ volts
B—Deviation <3.6%, ratio = 30.5, $E_{cc} = -10$ volts
C—Deviation <4.5%, ratio = 22, $E_{cc} = -7$ volts

$$R_1 < \left| \frac{E_{cc}}{I_1} - R_7 \right|$$

so as to prevent saturation of T_1 during pulsing time. It should be noticed that this will not prevent saturation caused by the trigger source.

10. Choose R_8 so that it satisfies the following inequalities:

$$\frac{R_1 R_7(\beta-1)}{R_7+(1-\alpha)R_1} > R_8 >> \beta R_7$$

The former part of the inequality satisfies the negative resistance criterion (that the circuit must satisfy to be a multivibrator at all) and the latter part of the inequality simulates a current drive at the base of T_1.

11. If R_b is the back-resistance of the diode used to decouple the trigger source from the circuit, then

$$\frac{(R_8+\beta R_7)R_4 R_5}{R_4 R_5+(R_4+R_5)(R_8+\beta R_7)} << R_b$$

or if

$$(R_8+\beta R_7) >> \frac{R_4 R_5}{R_4+R_5}$$

(which must be true if the assumption $V_{b10} \doteq V_{b11}$ is justifiable), then

$$\frac{R_4 R_5}{R_4+R_5} << R_b$$

Table III. Experimental Data for Fig. 6

Minimum Pulse Width, Microseconds	Maximum Pulse Width, Microseconds	% Jitter	C, Microfarads	Maximum Ratio
5	1,800	$\frac{5.6}{200}=2.8$	0.0147	360
5	1,400	$\frac{3.2}{170}=1.88$	0.01	280
5	1,070	$\frac{1.2}{100}=1.2$	0.0047	214
5	365	$\frac{0.7}{100}=0.7$	0.0022	73
5	120	$\frac{0.4}{100}=0.4$	0.0010	24
5	60	$\frac{0.1}{45}=0.22$	0.0005	12

This is one condition that the choice of the potentiometer (R_4+R_5) must satisfy. There is still one more degree of freedom left in the choise of (R_4+R_5). This other degree of freedom may be decided from among a group of practical considerations such as drain on the power supplies, available ohmic values of the potentiometer, wattage dissipation that can be withstood, etc.

12. When

$$I_2 R_7 = V_{b10} \tag{9}$$

T_1 starts to conduct in the absence of trigger. This is the point at which the output pulse width should start to diminish. Hence the maximum pulse width is obtained by evaluating equation 1 with the use of equation 9. Then using specification 7, for the value of the capacitance C

$$C = \frac{t_{0\,\max}}{R_6 \ln\left(1-\frac{V_{e0}}{E_{cc}}\right) + \ln\left[1+\frac{\beta R_1 I_2 R_7}{(R_8+\beta R_7)(E_{cc}-V_{e0})}\right]}$$

This completes the design procedure for the circuit itself.

Cascade Operation Considerations

Fig. 1(B) shows the simplest and the most desirable coupling circuit to be used for single-stage operation, as it offers the fewest restrictions on the circuit performance. If the source cannot tolerate direct current through it, then the circuit of Fig. 3 should be used.

If τ_c and τ_n denote the time constants of this circuit when the diode is conducting and when the diode is not conducting, respectively, the circuit parameters should be so chosen that $\tau_c > 10\tau$ (where τ is the time constant of input pulse rise time) *and* $\tau_n << \tau_p$. The former condition prevents too much loss in effective trigger height.[5] The latter condition ensures the return of the circuit to normality before the next trigger pulse arrives.

The case of several stages of cascade can be handled with the same circuit coupling as that of Fig. 3, except that here the output resistance of the preceding stage and the input resistance of the following stage will replace R_g and R_L, respectively. In practice, the presence of the diode was found necessary to make the output pulse width independent of trigger duration and height.

When very long delays are needed they may be obtained by operating the common emitter circuits in cascade. Thus with such an operation the range of delays can be made quite large without introducing appreciable error.

Experimental Correlation

Fig. 4 shows a large linear range of output pulse width with the voltage V_{b10} as predicted by the analysis. Table I shows the value of the components used and Table II shows the correlation between the values of the output pulse width calculated with the use of equation 1 and the values obtained experimentally from a curve like that of Fig. 4. The correlation is as good as can be expected. The explanation for departure from linearity at large and small values of V_{b10} follows readily from theory.

In vacuum-tube circuits of the cathode-coupled linear-time-delay type, ratios of the maximum-to-minimum output pulse

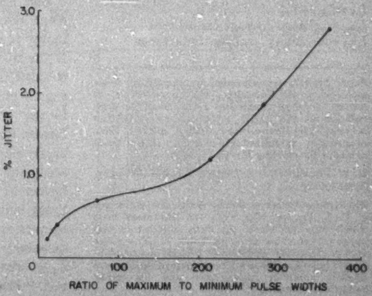

Fig. 6. Variation of jitter with output-pulse-width ratio

width obtainable of 10, or at most 20, have been possible. In the transistor circuit under consideration ratios as high as 800 have been obtained from a single circuit. Restricting deviations from linearity to be within 3%, a ratio as high as 31 has been realized. (Deviation here is defined as the ratio, at any particular point, of the difference between the ordinate of the experimental curve and that of the best fitting linear line divided by the experimental ordinate at the point.) Fig. 4 shows one of these curves.

Fig. 5 shows the output pulse duration as a function of the base voltage V_{b10} for the second stage of a 2-stage cascade circuit where the first stage is triggering the second stage without the use of an auxiliary amplifier.

As Table III indicates, the minimum pulse width obtained from the circuit is independent of the value of C used, whereas the maximum pulse width varies linearly with C. The former fact confirms the analysis that the fundamental limitation on minimum pulse width is imposed largely by device parameters. Thus it would seem possible to obtain large ratios of maximum-to-minimum pulse width limited only by the value of the capacitance used. The maximum value of C is determined in any practical case by the amount of jitter that can be tolerated. Fig. 6 shows an experimental curve of the maximum ratio versus percentage jitter based on the figures from Table III. It might be mentioned that the circuit configuration chosen minimized jitter.

Conclusions

Analysis and detailed design procedure for a transistor linear-delay circuit, together with some fundamental limits on the performance of the circuit, have been presented. The range of maximum-to-minimum pulse widths obtained is quite phenomenal.

An Equivalent Circuit for Transformers in Which Nonlinear Effects Are Present

H. W. LORD
FELLOW AIEE

TEXTBOOKS dealing with the subjects of transformer theory and design generally use the T-equivalent circuit to represent the inductive parameters of a transformer. This paper will point out a limitation of the T-equivalent circuit and will show that the π-equivalent circuit has no such limitation.

Nomenclature

n = transformer turns ratio (secondary turns/primary turns)
L_P = Total primary inductance = $L_{P,l}+L_m/n^2$
$L_S=L_{S,l}+L_m$
$L_{P,l}$ = primary leakage inductance
$L_{S,l}$ = secondary leakage inductance
$L_l=n^2L_{P,l}+L_{S,l}$ = total leakage inductance referred to the secondary
$L_{P,m}$ = magnetizing inductance of primary core portion
$L_{S,m}$ = magnetizing inductance of secondary core portion
L_m = magnetizing inductance of entire core referred to secondary
$\mathcal{R}_P$ = reluctance of primary core portion
$\mathcal{R}_S$ = reluctance of secondary core portion
$\mathcal{R}_l$ = reluctance of leakage flux path

The Well-Known T-Equivalent Circuit

Fig. 1 shows the well-known T-equivalent circuit which has been used for many years to represent a transformer. If the transformer it represents is a close-coupled transformer, such as a conventional public-utility distribution transformer or a small power-supply transformer for electronic circuits, this equivalent circuit is generally adequate for analyzing the performance of the transformer in a system. The total magnetizing inductance, L_m, is determined by an open-circuit test. The primary and secondary leakage inductances, $L_{P,l}$ and $L_{S,l}$, are determined by a short-circuit test. The short-circuit test determines the total leakage inductance, L_l. However, when reflected to the same transformer terminals, one half of this total is arbitrarily assigned to the primary leakage inductance and the other half is assigned to the secondary leakage inductance; i.e., it is assumed that $n^2L_{P,l}=L_{S,l}=L_l/2$. (Since this paper deals mainly with the inductive elements of the equivalent circuit, details for determining the equivalent resistive or loss elements will not be discussed.)

When the value of L_l is only a fraction of L_m, as it is in close-coupled transformers, the error introduced by assuming that $n^2L_{P,l}=L_{S,l}$, even though such equality may not exist, is small. In fact, for such transformers, the equivalent circircuit (neglecting losses) is often simplified to that of Fig. 2 in order to simplify the circuit analysis.

When a transformer involved in an analysis is of the type which designers of power-frequency transformers call high-reactance (high leakage inductance) trans-

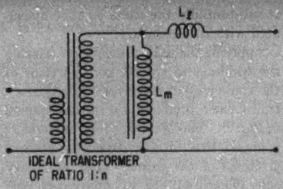

Fig. 2. Simplified L-equivalent circuit

formers and which radio engineers call loose-coupled transformers, the equivalent circuit of Fig. 2 can seldom be used. Moreover, in this type of transformer, if the reluctances of the magnetic circuits associated with the primary and secondary coils differ substantially, the T-equivalent circuit with $n^2L_{P,l}$ and $L_{S,l}$ equal is no longer valid, and an assumption that they are equal leads to substantial errors in an analysis.

When nonlinearities due to core-saturation effects are present, the T-equivalent circuit provides no means for separating the saturation effects associated with the primary-core portions from those associated with the secondary-core portions.

For a low-reactance transformer of normal design, saturation effects have little or no effect on the secondary voltage under various load conditions. However, in these types, the amount of load current and its phase angle with respect to the induced voltage cause the flux densities in certain portions of the core to be different from those in other core portions. For this reason, the T-equivalent circuit is not suitable for analyzing the effects of loading upon flux-density-dependent characteristics of a low-reactance transformer. These effects include harmonic content of the exciting current, core losses, and noise due to magnetostriction.

Saturation effects in the secondary core portions of high-reactance transformers affect both the secondary voltage waveforms and the effective primary-to-secondary voltage ratios. The T-equivalent circuit is practically useless for representing a high-reactance transformer when secondary-core-portion saturation effects are present.

The T-equivalent circuit bears no direct relationship to physical portions of the transformer structure. To many engineers, this may not constitute a serious handicap. But there are probably many others who are disturbed by the lack of direct relationships between the physical properties and dimensions of a device and a circuit which is considered to be its equivalent.

The π-Equivalent Circuit

Fig. 3 shows a π-equivalent circuit for a transformer which is the counterpart of the T-circuit of Fig. 1. The earliest, generally available, published material showing this transformer equivalent circuit is reference 1 which points out that: "Figure 13 is probably more adaptable to the representation of saturation characteristics of the core than Figure 15a." (Fig. 13 of the reference shows a π-equivalent circuit and Fig. 15a shows a T-equivalent circuit.) Actually, as will be clear from the following sections, this quotation is an understatement of the usefulness of this π-equivalent circuit.

If, for the sake of simplicity, the effects of losses are neglected, the π-equivalent circuit reduces to that of Fig. 4.

π-Equivalent Circuit Related to Physical Transformer Structures

One advantage of the π-equivalent circuit is that the magnetic reluctances of certain portions of the transformer-core structure, plus the windings associated with them, determine the values of the inductive elements of the equivalent circuit, and it is not necessary to assume any fixed ratios of their values. Fig. 5 represents the core and coils of a high-reactance transformer. The magnetic reluctances of core portions associated with the primary, secondary, and leakage inductances are labeled $\mathcal{R}_P$, $\mathcal{R}_S$, and $\mathcal{R}_l$ respectively. The reluctance $\mathcal{R}_P$ of the indicated core portion and the turns of the primary coil are factors which determine the value of primary magnetizing

inductance $L_{P,m}$. The reluctance $\mathcal{R}_S$ and the turns of the secondary coil similarly determine the value of secondary magnetizing inductance, $L_{S,m}$. (In Figs. 5–7, an air gap has been shown in the secondary-core portions merely to indicate one factor which can cause $\mathcal{R}_P$ and $\mathcal{R}_S$ to be different.) The reluctance $\mathcal{R}_l$ and the turns of the secondary coil are factors which determine the leakage inductance referred to the secondary, L_l.

If the lengths, areas, and core materials constituting the primary and secondary magnetic circuits are all identical, then the inductances $n^2L_{P,m}$ and $L_{S,m}$ will be equal for equal flux densities. However, if identical conditions do not exist, such as through inequalities of core areas, flux densities, lengths of flux paths, or unequal air gaps in the primary- and secondary-core portions, then the inductances $n^2L_{P,m}$ and $L_{S,m}$ may not be equal.

With these relationships between the physical portions of the transformer and the inductive elements of the π-equivalent clearly established for a relatively simple form of high-leakage-reactance transformer, a series of changes in coil and core configurations will serve to demonstrate that similar direct relationships exist even in a conventional low-reactance transformer.

Fig. 6 shows two coil configurations on the same core configuration which are magnetically equivalent in respect to core fluxes and reluctances; i.e., the differences due to leakage fluxes external to the core structure are disregarded. Fig. 6(A) illustrates a well-known type of high-reactance transformer. High-reactance transformers illustrated by Fig. 6(B) are not so well known. This latter type is employed when it is desirable to keep the air-path leakage flux between primary and secondary to a minimum. Note that although portions of the primary coil conductors which are external to the core window are in different positions in Fig. 6(B) than in Fig. 6(A), they have the same portions of their respective core structures associated with them. From this fact it can be concluded that it is only the relative positions of the primary and secondary coil conductors in the core window that determine the portions of the core with which they are associated.

The configurations of Figs. 5 and 6 are commonly referred to as "core-type" high-reactance transformers. Fig. 7 is a "shell-type" high-reactance transformer derived from Fig. 6(B). It is not a practical configuration, the usual shell-type high-reactance transformer being of the type derived from Fig. 5. However, Fig. 7 better serves the transition to the conventional low-reactance (close-coupled) transformer core and coil arrangement shown by Fig. 8. The leakage flux in low-reactance transformers is entirely in air as shown in this figure. However, the area of leakage flux path is not confined to the window as illustrated, but also includes the portions of the coil external to the window. This figure also shows that in the shell-type transformer with a single primary and single secondary, the actual length of core associated with the primary is substantially the same as that associated with the secondary.

Applying the same principles of relating the windings to specific core portions of the conventional core-type low-reactance transformer produces the results shown in Fig. 9. This is of particular interest as it shows that for the particular relative positions of the primary and secondary coils illustrated, the secondary-core portions are much longer than the primary-core portions. In normal designs of this coil arrangement, the secondary magnetizing inductance will therefore be less than the primary magnetizing inductance as reflected to the secondary. (Interchanging primary and secondary coil positions will, of course, cause the converse of this.) A similar condition will be found to exist in a shell-type transformer when the secondary consists of two coils of equal turns with the primary coil between them.

The foregoing examples for a variety of core and coil configurations demonstrate that it is possible to relate the magnetic characteristics of appropriate structural parts of a particular transformer to the inductive elements of a π-equivalent circuit for that transformer. The validity of this division of the core into primary- and secondary-core portions is further substantiated by experimental data which follow.

Methods for Determining Equivalent Circuit Parameters

The leakage inductance of a transformer under test is measured in the conventional manner as shown in Fig. 10. This particular arrangement of instruments is required when measuring high-reactance transformers in order to provide measurements which are insensitive to the effects of magnetizing currents required by core portions other than those associated with the leakage flux.

TRANSFORMER UNDER TEST WITH TURNS RATIO OF 1:n

a technique which is radically different from that usually employed when the magnetization characteristics of the entire core are determined by an open-circuit test. Fig. 11 is a schematic circuit diagram of a test circuit which provides data for determining the characteristics of $L_{P,m}$ and $L_{S,m}$. Both the primary and secondary are excited simultaneously with in-phase voltages E_S/n and E_S, respectively. When the proper transformer terminals are so excited, the leakage flux will be zero; therefore, the current flowing in the primary winding will be that required to excite the core portion associated with the primary, and the current flowing in the secondary will be that required to excite the core portion associated with the secondary. (These separate excitation currents do not necessarily flow under normal operating conditions.) If the core losses are small as compared with the reactive components of exciting current, the relationships given in Fig. 11 provide reasonably accurate values to use for the equivalent circuit. If the core losses are not negligible, then the wattmeter readings provide information for use in determining the values of resistances to be used as shunt elements in the equivalent circuit of Fig. 3 and for more accurately determining the values of the magnetizing inductance elements for the equivalent circuit.

Core-type transformers with primary and secondary coils on each leg have a core and coil configuration, the physical relationship of which to the π-equivalent is the least obvious of all of the simpler configurations. Also, as pointed out earlier, normal designs of this type call for an equivalent circuit whose shunt or magnetizing inductance elements are not equal. For these reasons, a core-type transformer was chosen to demonstrate how the test methods outlined are effective in determining the separate magnetizing characteristics of the three inductive components of the transformer which correspond with the three inductive elements of the π-equivalent circuit.

Two high-reactance 1-to-1-ratio core-type transformers were constructed, the respective coils of which were identical. They were similar in physical appearance to that depicted by Fig. 9 with the exception that magnetic shunts were placed between the primaries and secondaries in the position identified in Fig. 9 by the symbol $\mathcal{R}_l/2$, to provide high leakage inductance. The cores of these two units were substantially identical in over-all dimensions. However, in unit *A* an air gap was placed in the center of each yoke to increase the reluctance of the primary-core portions, whereas in unit *B* an air gap was placed in the center of each leg to increase the reluctance of the secondary-core portions.

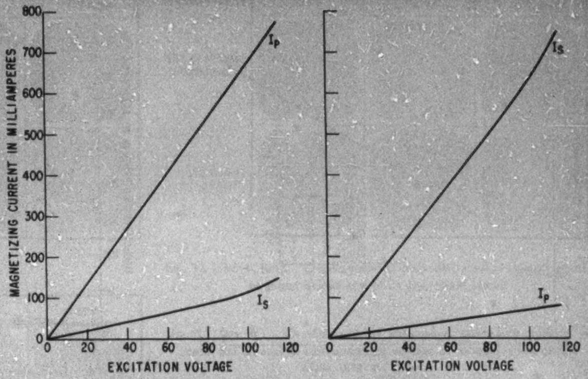

Fig. 12. Excitation volt-ampere characteristics

A—Test unit A, air gaps in yokes (parts of core associated with primary)
B—Test unit B, air gaps in legs, under coils (parts of core associated with secondary

The results of short-circuit impedance tests showed that the leakage inductance characteristics of the two units are approximately the same.

The results of primary and secondary magnetizing impedance tests of the two units are shown in Fig. 12. These data clearly show the effect of the position of the air gap with respect to the primary- and secondary-winding-core portions on the magnetization characteristics of the primary and of the secondary. In unit *A*, with the air gap in the yoke, the exciting current of the outer coil, which has been arbitrarily labelled the primary, is much higher than that of the secondary or inner coil. But in unit *B*, with the air gaps in the leg portions, the primary exciting current is very low while the secondary exciting current is high. Note also that the lower curve of unit *B*, which is a measure of the exciting requirements of the yoke-core material, shows values for corresponding voltages which are lower than those of the lower curve for unit *A*, which corresponds to the exciting current requirements of the core material of the leg sections. This relationship is consistent with the fact that the yoke-core portions are shorter than the leg-core portions; hence at a given flux density they should require lower volt-amperes of excitation than are required by the leg-core portions.

From the test results displayed by Fig. 12, it seems reasonable to draw the following conclusions:

1. The test method described in connection with Fig. 11 does provide a means for measuring the primary and secondary magnetization characteristics of a transformer.
2. It is possible, even in rather complex coil configurations, to relate certain core portions and their excitation requirements to appropriate coil windings.
3. The primary and secondary magnetizing impedances in certain transformer coil and core configurations are inherently unequal.
4. A direct relationship can be established between the magnetic reluctances of certain portions of the transformer-core structure and the inductive elements of its π-equivalent circuit.

Consideration of Saturation Effects

In some transformer applications the secondary-core portion may be operated in the saturation region at the same time that the primary is operating at somewhat lower flux densities. Such a mode of operation may arise from two effects which can be present either singly or in combination: (1) reduced cross section of the secondary-core portion compared with that of the primary as in a peaking transformer, and (2) an effective leading-power-factor load on the secondary, such as is present in regulator-type transformers and ballasts. Since the π-equivalent circuit separates the primary magnetizing inductance from the secondary magnetizing inductance, it provides a means for including the effects of these differences in the equivalent circuit. This can be done by having the shunt elements of the π-equivalent circuit which represent the primary and secondary exhibit the same degree of nonlinearity as is exhibited by

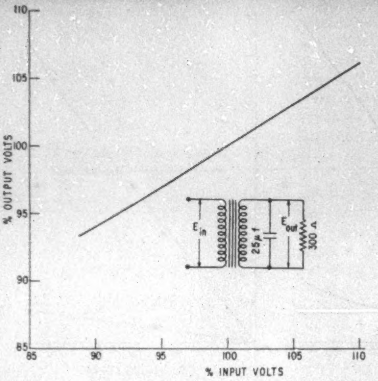

Fig. 13. Characteristics of modified unit A operating as an elementary voltage stabilizer

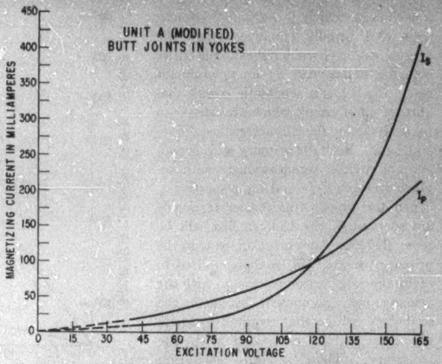

Fig. 14. Excitation volt-ampere characteristics of modified unit A over voltage ranges pertinent to its operation as a voltage stabilizer

the transformer of which it is designed to be an equivalent. The test method described in connection with Fig. 11 provides a means for determining the respective volt-ampere characteristics of the primary and of the secondary. It is required, of course, that the input voltages under test be carried high enough to include the highest voltage known to appear across a given winding under operating conditions. (When the secondary cross sections of the core is drastically reduced, as in a peaking transformer, it may not be possible to carry the test so as to bring the primary voltage to full excitation value. However, in this case, such a restriction is not serious since the primary magnetizing inductance plays no part in determining the output waveform characteristic, and therefore its effect can be neglected.)

The transformer identified as unit *A* exhibits regulating properties if its secondary is paralleled by a 25-microfarad capacitor and a resistance load of 300 ohms. Under these conditions, the secondary voltage was 156 volts with a primary input voltage of 118 volts. Fig. 13 shows the regulation curve of secondary voltage versus primary voltage over a range of 105–130 volts on the primary. (The air gaps in the yokes were reduced to butt joints in order to reduce the primary exciting current for these tests.) Fig. 14 shows the results of impedance tests on this unit to determine the proper volt-ampere characteristics required of the corresponding shunt impedances to use in a π-equivalent circuit for this transformer under these operating conditions.

Physical Equivalent Circuits and Their Operation

Owing to the close relationship between the π-equivalent circuit element and the transformer of which it is an equivalent, it is possible to construct physical equivalent circuits which perform in the same manner as their equivalent transformers. This can be done even though saturation effects are present in certain of the elements under operating conditions. The test results which follow provide graphic proof that this is possible. They also provide a convincing demonstration of the validity of this π-equivalent circuit.

Fig. 15 shows a schematic diagram of the equivalent circuit of the type of device selected to demonstrate this close tie between a high-reactance transformer and its equivalent circuit. The device is a ballast for arc-discharge types of lamps. This ballast consists of a high-reactance transformer with a capacitor in series with the transformer secondary and the arc-discharge lamp load.

The transformer parameters for three ballasts of widely different lamp loads were determined in accordance with the methods described in this paper. From the information obtained, coupled with the primary and secondary currents and voltages under both open-circuit and operating conditions, inductors and transformers for π-equivalent circuits were designed and built. The inductor elements for the equivalent circuits were then adjusted so that their volt-ampere characteristics corresponded very closely to the parameters of the particular transformer which they were designed to represent. The comparative results of elec-

Fig. 17 (above). Oscillograms of transformer secondary voltage of actual ballast and of corresponding voltage of its equivalent circuit

Fig. 18 (left). Oscillograms of voltage induced in test coils around magnetic shunts of actual ballast transformer and of voltage across series inductor of its equivalent circuit

trical measurements on these transformer ballasts and their respective equivalent circuits when operating into their rated lamp loads are shown in Table I. Considering the fact that nonlinear effects were present in the secondary-core portions of all of these units, and that the lamp loads also exhibit nonlinear volt-ampere characteristics, the close correspondence between the operating characteristics of the physical equivalent circuit and its real counterpart shown by Table I is quite good.

The results of oscillographic tests on one of the ballasts and its equivalent circuit are included in Figs. 16–18. These show that the differences between corresponding waveshapes of the ballast and the equivalent circuit are extremely small. Fig. 18 is particularly interesting as it demonstrates the accuracy with which the series linear inductor duplicates the effect of the magnetic shunts in the actual high-reactance transformer.

Conclusions

The seldom-used π-equivalent circuit has been shown to be capable of accurately representing a transformer in which nonlinear effects are present. Also, the inductive elements of this equivalent circuit have been shown to be directly relatable to the magnetic characteristics of certain portions of the transformer core. In addition, a physical π-equivalent circuit can be constructed which will operate in almost precisely the same manner as the transformer of which it is an equivalent. In view of these several advantages, the π-equivalent circuit should be employed in analyzing the operation of circuits which include a transformer as a circuit element when the transformer is a high-reactance type and/or when saturation effects must be taken into account in the analysis.

When saturation effects are employed in a high-reactance transformer to provide a desired operating characteristic, the π-equivalent circuit, with its accurate portrayal of a transformer, provides a means for expediting the development of the required transformer. Since the parameters of a developmental physical equivalent circuit can be varied independently, the transformer designer can vary the parameters of the transformer equivalent circuit along with other circuit parameters, until the complete circuit provides the desired operating characteristics. The transformer design procedure then becomes one of attaining a core and coil configuration with magnetization characteristics which correspond to the pertinent elements of the developmental equivalent circuit. The close relaships between the transformer-core portions and the corresponding elements of the equivalent circuit enable the designer to use the pertinent information supplied by the developmental equivalent circuit, coupled with the basic core material's magnetic properties, to determine the proper physical shapes and dimensions of various parts of the transformer-core structure which will provide the desired magnetization characteristics. Of course, this part of the design procedure may show that the magnetic properties of the magnetic material the designer wishes to employ impose restrictions which prohibit the attainment of the desired result. However, it is much better to find it out through the use of a developmental equivalent circuit and a bit of calculation than to have to draw the same conclusion after a time-consuming series of tests on a number of successive developmental transformer designs.

It is hoped that this paper, coupled with the increased interest in nonlinear magnetics, will create such an interest in the π-equivalent circuit for transformers that it will soon become generally recognized as the proper tool to use in the analysis and design of transformers in which nonlinear effects are present.

Discussion

Reuben Lee (Westinghouse Electric Corporation, Baltimore, Md.): Mr. Lord has demonstrated that the π-circuit is a better equivalent than the T-circuit for high-reactance transformers. This paper shows remarkably close equivalence in the test results of Table I. This equivalence is particularly appropriate for the several applications which have been chosen.

One minor point which might be omitted without prejudice to the main argument of the paper concerns the assumption that in the T-equivalent circuit the primary and secondary leakage inductances are equal when referred to the same winding. This is only true for especially designed coils, and it is by no means true in the general case. Also, it is not necessary in the equivalent T-circuit, where it is applicable, to regard the leakage inductances of the two windings as equal.

H. W. Lord: I agree with Mr. Lee's statement that in the T-equivalent circuit the primary and secondary leakage inductances are not required to be equal nor are they equal in the general case. I did not intend to imply that such equality existed, in the general case, by the statement in the paper "--it is assumed that $n^2L_{P,l}=L_{S,l}=L_l/2$."

The foregoing statement was made in connection with the determination, by conventional test measurements, of the values to use for $L_{P,l}$ and $L_{S,l}$ in the T-equivalent circuit of a given transformer. In a close-coupled transformer, the coil geometry is generally considered to be the principal factor which determines the relative magnitude of the primary and secondary leakage inductances. The methods described in the literature for measuring their relative values are characterized as very complicated (reference 1, pp. 354–55) and such measurements as being subject to large errors because they require a measurement of the magnetizing inductance to an accuracy of about 0.01% in order to secure a 5% accuracy in the ratio of their magnetidues (reference 1, p. 454). Therefore, textbooks (reference 1, 355 and reference 2, p. 188) state that when it is necessary to make any assumptions as to their relative magnitudes, it is often assumed as an approximation that they are equal. It was against this background of practice in relation to the T-equivalent circuit that the statement referred to by Mr. Lee was made in the paper.

Considerations of the equivalency of the T- and π-circuits show that if the π-equivalent-circuit parameters are determined by the test methods described in the paper for close-coupled transformers similar to that shown by Fig. 9 and are then converted to their equivalent T-circuits, one finds that the ratios of the primary to secondary leakage inductances of such equivalent T-circuits are determined by the ratios of the primary to secondary magnetizing inductances of the π-circuit. With this approach, the coil geometry does not determine the relative magnitudes of the primary and secondary leakage inductances since, with a fixed coil geometry, a change in core reluctances such as in test units *A* and *B* of the paper, will produce a change in the relative magnitudes of the primary and secondary leakage inductances of the T-equivalent circuit. It was because of this difference between T-equivalent circuits arrived at by the conventional coil geometry approach and by the magnetizing inductance approach, that the statements were made in the paper concerning the deficiency of the T-equivalent circuit for close-coupled transformers.

SPUD, A Stored-Program Universal Demonstrator for Computer Training

M. RASPANTI
NONMEMBER AIEE

CONSIDERABLE difficulty is usually encountered by the novice in understanding how stored-program information-processing systems operate, and how they can be programed. While conventional teaching tools are definitely inadequate in this case, the use of a commercial computer for demonstrations does not provide an ideal solution either, because the machine tends to overwhelm the novice with its speed and complexity. A satisfactory solution has been found in SPUD (Stored-Program Universal Demonstrator), a stored-program relay machine designed specifically as a teaching aid, complicated enough to stimulate the novice but still easy to grasp in its entirety.

Wired and Stored Logic

The basic principles of information-processing machines can be reviewed very conveniently by means of an analogy. Assume that we want to train a native from some uncivilized region. To enable him to perform some specific task, we must somehow show him exactly what to do under various conditions. At the end of the training, we will have established in the native's brain the mental paths that he needs to handle the job on his own. In a somewhat similar fashion, we can design a machine to perform a specific task by connecting a number of switching devices in such a way as to create the necessary paths of mechanized reasoning. In this case, we say that the machine uses only "wired logic" because the intelligence to perform a specific job resides in the wiring of the machine. This arrangement has an inherent lack of flexibility: an extensive rewiring or even a major redesign may be required to modify the task to be performed by the machine.

The native of the analogy suffers from a similar disadvantage: he must be trained again whenever a new task is assigned to him. This difficulty can be eliminated if we can establish some language with which to communicate with our native. Instead of giving him a specialized training for each specific job, we will train him once and for all to understand and execute any one of a set of instructions or orders. We can then

enable him to perform a specific job by writing an appropriate sequence of instructions in the language that he understands. One such sequence of instructions, or program, is shown in Fig. 1. In the DO type of orders, the letters *E*, *B*, *A*, etc., are used to designate elementary actions to be performed by the native, who is also instructed to advance to the next order. At the end of the program, a GO type of order instructs the native to transfer to some specified instruction. Observe that, in any particular program, some of the orders in the native's repertoire may not be used at all, while others may be used quite frequently.

The type of program shown in Fig. 1 can prescribe only a single line of action. A very flexible type of program can be written if we train our native to examine or "read" any one of a number of situations $y_1, y_2, \ldots, y_t$ and to determine which of n possible cases exists at the time. We can then give the native very definite instructions for each of the n possible cases. If each situation results in either a "yes" or a "no" case, we can write a program of the type shown in Fig. 2.

Regardless of the pattern in which the program branches out, the instructions can be submitted to the native in a very orderly fashion by means of a blank program form of the type shown in Fig. 3. A complete instruction or "word" can be written in each blank line or "word location," which is uniquely identified by a number or "address." Fig. 4 shows the program of Fig. 2 in the form in which it would be submitted to the native.

Merely by following to the letter the instructions of the program, the native is capable of performing some specific task under the various conditions that may arise. The intelligence to perform the specific task is not any longer in the native's brain; it resides, instead, in the form in which the program has been written. Without any additional training, the same native can perform an entirely different task if he is supplied with the appropriate program. In fact, the native can perform any task for which a program can be written in his language using no more than 16 "words."

In a similar fashion, a program-controlled machine uses general-purpose wired logic to interpret and execute any one of a number of instructions. For the specific tasks to be performed, programs are written in machine language and recorded in some storage or memory unit, from which they are fed to the implementing circuitry of the machine. We

say now that the machine uses a combination of wired and "stored" logic.

Functional Description

Spud is a miniature information-processing machine that is capable of completely automatic operation under the control of a program stored in a punched card. Fig. 5 shows a blank program card with 32 9-bit word locations. In Fig. 6 (A) a punched card is shown partially inserted in the program storage unit; in Fig. 6(B), it is completely inserted. Fig. 7 labels in detail the equipment mounted on the front panel and the recessed side panel shown in Fig. 6(A). The over-all dimensions are 24 by 34 by 12 inches; the weight is 110 pounds.

The major units of the machine are

1. The program storage.
2. The control unit, which includes the order register and the address register.
3. The erasable memory.
4. The input unit.
5. The output unit.

Only the program storage will be described in some detail; the remaining units will be given a brief functional description

The Program Storage

As shown in Fig. 8, the program storage consists of two matrices, each with 16 rows and 9 columns; the rows correspond to word locations, the columns to bits within a word. At each cross-point, a contact element tends to connect the corresponding row and column. Whether a connection is actually established depends on whether a corresponding hole has been punched on the program card, which is inserted between the contact elements and the columns.

At any one time, ground is applied to only one row via a selecting circuit.[1] This ground is allowed to appear only on those columns for which, along the grounded row, holes have been punched on the program card; e.g., a ground on row 15 will appear on column W_1 but not on W_9. The diodes are used to prevent ground backups. For instance, when row 15 is grounded, if no diodes were provided, the ground would be allowed to reach column W_9 over row 0, even though there is no hole at the cross-point of row 15 and column W_9. Thus, grounding a row reads out the corresponding word by converting a combination of punched holes on that row into a combination of ground signals on nine leads to the control unit.

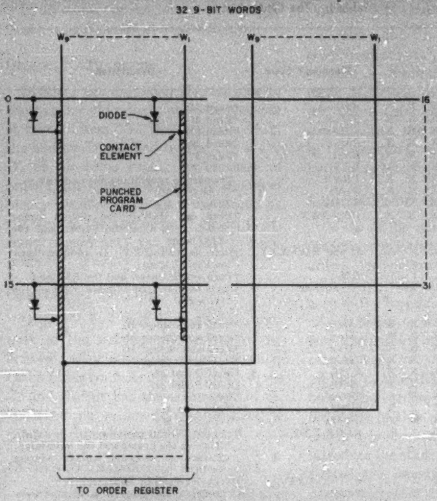
Fig. 7. Front and side panel arrangement



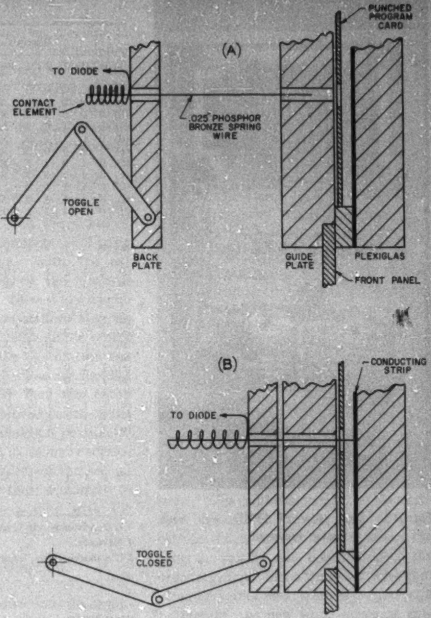


Fig. 8 (above). Electrical schematic of program storage

Fig. 9 (right). Mechanical schematic of program storage

Some mechanical details of the program storage are given in Fig. 9. Each contact element consists of a coil spring which continues into a straight wire along the axis of the coil. The 288 contact elements are mounted on a back plate, which can be moved toward or away from the front panel by means of a toggle controlled by the frame shown in Fig. 6(A) with the engraving "program storage." When the frame is in the position of Fig. 6(A), the back plate is furthest away from the front panel. The straight portions of the contact elements move through holes in a stationary guide plate mounted on the front panel. Eighteen conducting vertical strips are embedded in the back of a Plexiglas plate mounted on the front panel. When the toggle is open, Fig. 9(A), the straight wires retract into the guide holes; a program card can be dropped now in the slot between the guide plate and the Plexiglas plate. When the toggle is closed, Fig. 9(B), the straight wires make contact with the corresponding conducting strips wherever holes have been punched on the program card.

The Control Unit

The function of this unit is to interpret and execute the orders that are read out of the program storage, one at a time in synchronism with a clock pulse. The clock pulse may be generated manually by means of a push button plugged into a receptacle on the recessed side panel (Figs. 6(A) and 7). It may also be generated automatically about every second by means of a small motor, which actuates a set of contacts. The lamp labeled "clock" lights up whenever the clock pulse is present.

The order that is read out of the program storage is stored in the order register. While the clock pulse is present, the order is displayed on the nine lamps W_1 to W_9. The order register may also be controlled manually by means of the nine toggle switches under the lamps W_1 to W_9. By selecting either the manual or the automatic control for the clock and the order register, three modes of operation are made possible:

1. Automatic word (from the program storage) with manual clock (*AW-MK*).
2. Manual word (set on the toggle switches) with manual clock (*MW-MK*).
3. Automatic word with automatic clock (*AW-AK*).

The mode of operation is selected by means of the rotary switch mounted on the recessed side panel.

An important function of the control unit is to determine the address of the next order to be read out of the program storage. This address is stored in the address register and is transmitted to the program storage after the disappearance of the clock pulse. The address is displayed in binary form on the five lamps A_1 to A_5, and in decimal form on two Nixie* numerical indicators.

The Erasable Memory

This unit consists of five elements monitored by the five lamps M_1 to M_5. The machine can write "0" or "1" in any memory element; it can also read the information stored in any memory element.

The Input Unit

Information is fed into the machine via two input channels which are normally controlled by the keys P and Q. In addition to the up or "1" position and the down or "0" position, each key has a middle position to transfer the control of the corresponding channel to a remote switch plugged into two receptacles on the recessed side panel.

* If 0, advance. If 1, transfer to program storage address x.

† Advance.

‡ If a match exists, advance. If a mismatch exists, transfer to x.

THE OUTPUT UNIT

This unit comprises a buzzer and the lamps Z_1, Z_2, Z_3, RDO, SI, and RM. Normally, the machine gives out information as 3-bit words displayed on the lamps Z_1, Z_2, and Z_3; all the combinations are possible except 111. When the machine gives an output, the following actions take place:

1. The "read the output" lamp RDO lights up and the buzzer sounds to attract the attention of the operator.
2. The machine locks itself up making any subsequent clock pulses ineffective.

At the time the machine gives an output, it may also request the operator to set a new input on P and Q by lighting the "set the input" lamp SI. The operator acknowledges the output by pressing the release push button. This action extinguishes the lamps Z_1, Z_2, Z_3, SI, and RDO, shuts off the buzzer, and unlocks the machine.

The machine may also give out information by utilizing part or all of the erasable memory as an output unit. The actions that take place in this case are:

1. The "read the memory" lamp RM lights up and the buzzer sounds.
2. The machine locks itself up.

As for the previous case, the machine may request at the same time a new input by lighting the lamp SI. The operator acknowledges the output again by pressing the release push button. This action shuts off the buzzer, extinguishes the lamps RM and SI, and unlocks the machine. The state of the erasable memory is not affected in any way.

THE INTERNAL MECHANICAL ARRANGEMENT

Fig. 10 shows the arrangement of the equipment inside the machine. Twenty-nine relays are mounted behind the lower part of the front panel. The power supply and the motor for the automatic clock are mounted on the chassis at the bottom. All the connections to this chassis may be easily unplugged, and the chassis may be removed to give access to the relay terminals. The upper part of Fig. 10 shows the coil springs mounted on the back plate of the program storage. The nine diodes for each word location are mounted on a printed card of the type shown near the bottom of the machine. The diode cards are plugged into the connectors shown on either side of the back plate of the program storage. Access to the connector terminals is gained by removing the printed cards and rotating the hinged connector assemblies by 90 degrees toward the program storage.

The Order List

Table I lists all the orders that the machine can interpret and execute. For each order, the table gives the 9-bit binary code, an abbreviation or mnemonic code, and a brief description. The orders may be classified as follows.

ORDERS TO READ

Orders *a*, *b*, *c*, *d*, *e*, *f*, and *t* instruct the machine to read a specified memory element or input channel. If a "0" is read, the machine shall advance to the next address in the program storage. If a "1" is read, the machine shall transfer to the program storage address specified by the five bits W_5 (most significant) to W_1 (least significant).

ORDERS TO WRITE

Orders *h* and *i* instruct the machine to write "1" or "0," respectively, in the memory element specified by the bits W_3 to W_1.

Orders *u* and *v* instruct the machine to "copy" the state of input channel P or Q, respectively, into the memory element specified by the bits W_3 to W_1.

Order *y* instructs the machine to "copy" the bits W_4, W_3, and W_2 into the memory elements M_4, M_3, and M_2, respectively.

In all cases, the machine shall advance to the next program storage address.

ORDERS TO TRANSFER

Orders *g* and *z* instruct the machine to transfer unconditionally to some program storage address. In the case of order *g*, the address is specified by the bits W_5 to W_1 of the order itself. In the case of order *z*, the address is given by whatever binary number happens to be stored at the time in the five memory elements M_5 (most significant) to M_1 (least significant).

ORDERS TO READ OUT

Orders *j*, *k*, *l*, and *m* control the outputs of the machine as previously described; they all result in an advance. Order *w* can control only the output lamps Z_3 and Z_2 but has the advantage of resulting in an automatic transfer back to program storage address 00000.

ORDERS TO CHANGE

Orders *n*, *o*, *p*, and *q* instruct the machine to read and then change memory elements M_1, M_2, M_3, and M_4 respectively. If a "0" is read (before the change), the machine shall advance to the next program storage address. If a "1" is read, the machine shall transfer to the address specified by the five bits W_5 to W_1.

ORDERS TO MATCH

Orders *r* and *s* instruct the machine to read simultaneously input Q and memory element M_1, or input P and memory element M_2, respectively. If a match exists, the machine shall advance; if a mismatch exists, the machine shall transfer to the program storage address specified by the five bits W_5 to W_1.

8-BIT AND 9-BIT ORDERS

It should be noted that the group of orders *a* to *m* forms a complete set of basic orders for programing. With the exception of order *t* (RM_5–x), the result of each of the remaining orders *n* to *z* can be accomplished by a combination of orders from the first group. Since all the orders *a* to *m* have "0" in the W_9 bit, we can pretend at first that the machine handles only 8-bit orders and that the entire order list of the machine consists of the orders *a* to *m*. This makes it possible to introduce the students to the more sophisticated time-saving orders of the second group only after they have acquired sufficient facility in programing with the simpler orders of the first group.

The General Block Diagram

In the preceding two sections the organization of the machine and its "language" were discussed. This information can be co-ordinated now by referring to the block diagram of Fig. 11. Although relays are used in the machine, gate symbols are employed in the block diagram as convenient functional blocks.

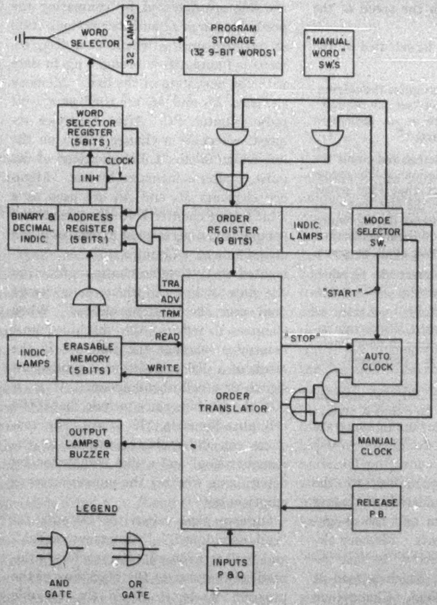

Fig. 11. General block diagram

Of particular importance is the address register. When either the *TRA* or the *TRM* lead is activated by the order translator, the address register is used to store information coming from the order register or from the erasable memory, respectively. When the *ADV* lead is activated, the address register acts as a counter and increases its contents by one.

Observe that there exists a loop going from the address register to the word selector register, the word selector, the program storage, the order register, the order translator, and back to the address register. If information were allowed to flow through this loop continuously, improper operation would result for the following reason. Upon arrival of a clock pulse, the order translator would cause a new address to appear in the address register. This address would be immediately transmitted to the word selector causing a new word to be read out of the program storage and transmitted to the order register. Since the clock pulse that generated the new address would still be present, the new word would be executed immediately. This, in turn, would generate a second new address, and so on, until the clock pulse disappeared. To insure an orderly processing of the orders, the loop previously mentioned is opened during the presence of the clock pulse by the inhibiting gate between the address register and the word selector register. Thus, the new address can reach the program storage only after the removal of the clock pulse. The new order is read into the order register, but it cannot be executed until the arrival of the next clock pulse.

Some Examples of Programs

The versatility of SPUD is sufficient to justify the term "universal." Not only is a fairly large variety of orders made available to the programer but, in addition, the programer can make the most out of the limited program storage capacity by utilizing multiple-action orders. As shown later in this section, universal program formats can be developed for certain types of combinational and sequential problems.

Twenty-five different types of orders are listed in Table I. If all the possible ways of assigning binary values to the *X*'s are considered, a total of 497 different

words is obtained. Thus, there are $497^{32} \cong 10^{86}$ different ways of filling out a program card; of these, only an extremely small percentage will yield meaningful programs. Even so, there should be at least several hundred thousand meaningful programs.

The capacity of the program storage is sufficiently small to be easily grasped in its entirety; at the same time, it is large enough to make possible many fairly complicated programs. The remainder of this section will be devoted to the discussion of some of the programs that have been written for the machine.

SERIAL ADDITION (FIG. 12)

This program will add two binary numbers of any length. Upon request from the machine, corresponding bits of the two numbers are set by the operator on the input switches P and Q, starting with the least significant bits. The carry is stored in memory element M_1; the sum is given out in serial form on the Z lamps by means of a 000 output for "0" and a 001 output for "1." At the beginning of the program, the machine requests the first pair of bits and, at the same time, gives out an output 000. This output is meaningless at this time, but it is impossible to light the *SI* lamp for an input request without lighting also the *RDO* lamp. The machine then reads the carry and the bits of the addend and augend, changes the carry, if necessary, gives the appropriate output, and requests a new input. This routine is repeated over and over again, until all the bits have been fed in.

LINE REGISTER

In this program, the "0" and "1" positions of input switch Q simulate the "on-hook" and "off-hook" conditions of a hypothetical telephone line. Up to four pulses may be "dialed" on this line by operating switch Q up and down at a rate that is compatible with the speed of the machine.

The requirements to be satisfied by the program are

1. The machine shall recognize the origination of a "call" and give a "service request" output, which will serve as an indication that "dialing" can be started.
2. The machine shall detect and count the dial pulses. Dial completion shall be recognized either by the fact that four pulses have been counted, or by the fact that some interval of time has elapsed during which the line has been in the "1" or off-hook state. A "dial completed" output shall be given.
3. The machine shall detect the termination of a "call" and give a "call terminated" output.
4. Once a call is originated, if a certain interval of time elapses before dialing starts, the machine shall give a "permanent signal" output.
5. If a "call" is abandoned, the machine shall detect this by the fact that a certain interval of time has elapsed during which the machine has been in the "0" or on-hook state.

The lower part of Fig. 13 illustrates the various cases to be considered; the upper part gives the program and the assignment of memory elements. Memory element M_1 is used to record the last observed state of line Q, which is read at discrete intervals of time. Changes on the line are detected by comparing the present state of Q and its previous state as recorded in M_1; whenever a disagreement is found, M_1 is brought up to date with the new state of the line. Memory elements M_2 and M_3 are used as a 2-bit pulse counter *PC*. After a service request, whenever a change occurs on the line from "0" to "1," the content of the pulse counter is increased by one. Memory elements M_4 and M_5 are used as a 2-bit timing counter T to recognize a dial completion, a permanent signal, or a call abandonment. Counter T is incremented every time no change is found in the state of line Q; whenever a change does occur, the counter is cleared. When counter T recyles, the machine must determine whether the time-out is the result of a dial completion, a permanent signal, or a call abandonment. If M_1 is "0," the machine can conclude that it is a call abandonment. If $M_1 = 1$, the machine can differentiate between a permanent signal and a dial completion by determining whether the pulse counter is empty or not

Observe that, after the outputs for "call abandoned," "permanent signal," and "call terminated," the machine automatically returns to the beginning of the program where it clears the erasable

Fig. 14 (left). Universal program for a 4-variable combinational problem

Fig. 15 (above). Universal program for a sequential problem with one input and eight memory states

memory before handling a new "call" on line Q.

4-VARIABLE COMBINATIONAL PROBLEMS

It is possible to write a general type of program based on the structure of the truth table shown in Fig. 14(A) for a Boolean function of four variables *x*, *y*, *z*, and *w*. Each of the f_i entries may be either "0" or "1." Fig. 14(B) shows the program and the assignment of the memory elements. At address 0, the machine requests the operator to set the binary variables *x* and *y* in input switches *P* and *Q*, respectively. The machine copies the values of *P* and *Q* into memory elements M_4 and M_3 (addresses 1 and 2), and asks the operator to set the remaining variables *z* and *w* in *P* and *Q* (address 3). The values of *P* and *Q* are copied then into memory elements M_2 and M_1 (addresses 4 and 5). The erasable memory contains now the complete 4-variable combination for which an output is required. When a "1" is prefixed to this combination (address 6), an address is formed which uniquely identifies one of the word locations 16 to 31. Thus, there is a one-to-one relationship between these locations and the 16 entries of the truth table. At address 7, the machine is instructed to transfer to the address stored in the erasable memory. Each of the word locations 16 to 31 contains an *RDOR* order which will give as an output the value of the function to be realized for the corresponding 4-variable combination. The machine automatically transfers to address 0 and is ready to handle a new combination of variables. Observe that the universal program of Fig. 14(B) can be adapted to any specific 4-variable Boolean function merely by assigning binary values to the f_i's.

SEQUENTIAL PROBLEMS

Fig. 15(A) shows the state table for a sequential problem with one input and eight memory states. At the intersection of a row and a column, there is a double entry (m_i, n_{i+1}), where m_i stands for a 3-bit combination defining the "next state of the memory",[2] and n_{i+1} stands for a 2-bit output combination. The only restrictions are

1. When the "present state of the memory" is 000 and the input is 0, the next state of the memory" is still 000 and no output is required.
2. Only four output combinations are available.

Within these restrictions, which result from the limited capacity of the machine, it is possible to write a general type of program based only on the structure of the state table. Such a program is shown in Fig. 15(B) together with the assignment of the memory elements. The first two steps of the program instruct the machine to copy the input *P* into M_5 and to transfer to whatever address happens to be in the erasable memory. Observe that when the power switch is first turned on, all the memory elements

M_1 to M_5 are in the "0" state. Therefore, as long as the input P is "0," the machine will shuttle between addresses 0 and 1. When the input P is changed to "1," the machine will transfer to address 16 (10000 in binary form), where it will write the "next state of the memory" m_{16} in M_4, M_3, and M_2. Assume, as an example, that $m_{16}=011$. In this case, the machine will write 011 in M_4, M_3, and M_2, and will advance. At address 17, the machine sounds the buzzer, reads out the 2-bit output n_{17}, and locks itself up. Even though the *SI* lamp does not go on, the operator must interpret the buzzer as a request to set the next input in P. When the operator presses the release button, the machine automatically transfers to address 0, where it copies P into M_5. It advances then to address 1 where it is instructed to transfer to the address stored in the erasable memory. If $P=0$, the machine transfers to 6 (00110 in binary form); if $P=1$, the machine transfers to 22 (10110 in binary form). The "next state of the memory" will be written in M_4, M_3, and M_2, an output will be given, and the routine will start all over again.

A program card punched in accordance with the universal program of Fig. 15 can be adapted to any specific problem merely by entering the required 3-bit m_i combinations and the 2-bit n_{i+1} combinations. The same program, of course, can be applied to a sequential problem requiring fewer states. In a similar fashion, a general type of program can be written for a sequential problem with two inputs and four memory states.

Conclusions

The machine described can facilitate considerably the teaching of programing principles for information-processing machines. It offers the student an opportunity to develop many interesting programs and to test their inplementation in a step-by-step fashion. The machine provides also an abstract model that can be a useful tool by itself.

Experience with Long-Distance Television Fields Used for Retransmission

W. L. BRAUN
MEMBER AIEE

IT HAS BEEN KNOWN for some time that long-distance (100–150 miles) very-high frequency propagation exists, and is capable of wide-band performance. This paper follows the empirical investigation of these fields to their ultimate use as signal sources for a community antenna system (CATV) and a television station (WSVA-TV).

The engineering staff of WSVA, Harrisonburg, Va., investigated frequency-modulated signal reception from April 1946 to December 1947. The results of these tests were to be applied to the siting problem of WSVA-FM. These field measurements indicated the existence of signals well beyond the limits generally assumed at the time. Various projects of high priority prevented the continuation of this project at that time. This program was reopened in August 1949 with the addition of television signal observation. Earlier conclusions as to the presence of these long-distance fields were substantiated. It was found that the stability of these signals was far greater than had been expected. No serious attempt was made to make a scientific investigation of the nature of these fields, except to investigate them by observation.

Harrisonburg is located in a natural bowl, behind two mountain ranges of the Appalachian chain, approximately 3,500 feet below horizon. The nearest sources of television signals in 1950 were Richmond, Va., and Washington, D. C. A few of the local residents attempted to receive these stations directly, but the results were unsatisfactory. It was felt that this situation justified the installation of a community antenna system (CATV). Field research was commenced immediately, following the guide of the information that had been accumulated previously. Since the nearest mountain range was approximately 8 airline miles distant, it seemed advisable to search the local area about the city to see if satisfactory reception could be found. It was discovered immediately that any site had to be explored in detail to evaluate it, as the fine-grain variation of the signal on a given site was quite substantial. It had been presumed that the greatest elevation of site would produce the largest signal. This did not prove to be an infallible rule. It was proved equally incorrect to assume that the signal increased with increasing height to the free space value. The actual siting situation can be summarized as follows:

1. The foreground clearance to the nearest obstruction must be reasonably uniform.
2. The shape of the foreground terrain slope is important.
3. The signal increases with height in Fresnel-zone fashion to a maximum, then minimum, then to a new maximum, but with each new maximum decreasing in intensity over the first.
4. The signal maximum is localized for a given site in height, width, and depth, and has to be located empirically.
5. The signal maximum outlined in items 3 and 4 is frequency-sensitive: 12- to 9-foot average for channels 7 through 13 and 40- to 35-foot average for channels 2 through 6.
6. Due to item 4, the position and size of the antenna aperature to be used must not exceed the signal "capsule."
7. The time-fading factor within this signal capsule is better than in an area outside it.
8. This is a small area phenomena, and since the time-fading factor is superimposed over the top of the exploration, great care must be taken to repeat the measurements enough times to assure the siting of the optimum location.
9. The signal gain possible by this technique is substantial, often as much as 15 db (decibels).

The optimum location could be gen-

Paper 59-674, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., May 19–21, 1959. Manuscript submitted September 19, 1958; made available for printing March 26, 1959.

W. L. Braun is with WSVA Shenandoah Valley Broadcasting, Inc., Harrisonburg, Va.

The author wishes to acknowledge the assistance of the following engineers who participated in the program described in this paper: Thomas B. Jones, J. Maxwell Foley, Ira T. Lowe, Robert C. Jackson.

erally described as the forefront of an elevated location, just before the crest of the elevation, with the slope of the forefront of this location approximating any of the curves possessing a focus accessible by the antennas. The further this condition prevailed before the major obstruction, the more nearly optimum location for one channel on a given bearing did not necessarily fit for another channel on the same bearing. In one case it was nearly 300 yards away.

Table I. Circuit Transmission Losses

Channel No.	Station Location	Length of Path, Air Miles	Path Loss, Db[1]
4	Washington, D. C.	90.0	135
5	Washington, D. C.	85.0	128
7	Washington, D. C.	90.0	145
8	Petersburg, Va.	98.5	149
9	Washington, D. C.	89.5	141
10	Roanoke, Va.	142.0	148
12	Richmond, Va.	93.5	135

The signal intensity at this optimum site was too low to deliver a satisfactory picture with a dipole antenna. It was felt that at least 20 db of signal improvement was necessary to achieve a satisfactory picture. A figure of 18 db was assigned to obtain as antenna gain over a dipole. The remaining gain was to be obtained by reduction of preamplifier noise figure and reduction of transmission-line loss by installing the preamplifier at the antenna terminals. All these proved to be reasonable goals.

A few interesting problems developed in the construction of antennas for this gain. This first antennas tried were 10-wavelength-per-leg horizontal rhombics. The first of these antennas performed satisfactorily, but did not deliver the calculated gain by 25% (voltage). This was found to be due to the excessive size of the rhombic exceeding the signal capsule. A longer rhombic was tried with 20 wavelengths per leg, but the major lobe split, and the resultant gain was very low. An assessment of the problem indicated the need for a compact antenna with gain in all three co-ordinate directions. A preliminary paper design indicated that arrays of yagi antennas, close spaced, would solve the problem. The first antenna was an array of 8–8-element yagi antennas with 0.62-wavelength colinear spacing and 0.75-wavelength vertical spacing (entire array was two high and four wide). This antenna produced its calculated gain when propagation conditions were good, but deteriorated somewhat when propagation conditions were poor. This was determined by making interarray phase measurements on the arriving signal. By very careful location of the array in the signal capsule, satisfactory results were obtained most of the time. A voltage standing wave ratio measurement of the completed array indicated a maximum value of 2 to 1 without any compensation other than simple matching. By the use of very simple networks, the voltage standing wave ratio was reduced to 1.5 to 1.

Two years of experience, until June 1953, indicated the following:

1. General level of night signal was 6–10 db higher than at the day signal.
2. The signal was least consistent about sunset.
3. Heavy overcast accompanied by high relative humidity always increased the median signal and reduced the variations about the median.
4. Occasionally the propagation would go through quick and deep fades for very short periods of time (not to be confused with aircraft flutter).
5. Reliability of circuits was excellent. Down-time was less than 0.2% on the poorest circuit.
6. Rhombics produced a characteristic "transient distortion," making their use less than desirable for this purpose.

The last item proved to be a difficult one to accept, but several years later this was found to be entirely true, and due in part to the phase shift of component parts of the signal over the length of the rhombic.

When WSVA-TV was constructed, it seemed advisable to use this system of signal source, as the television station was to be located on a very remote mountain top, 60 miles and two mountain ranges away from the nearest American Telephone and Telegraph interconnection point. Initial experiments on the television mountain top indicated a similar signal situation to that experienced at the community antenna site just under discussion, except that the median field was about 15 db higher. This site was 2,000 feet higher and 11 miles closer to the stations to be received than the CATV receiving site. It is interesting to note that the same signal capsule existed on the mountain site, but was less pronounced in the effect on the location of such a capsule. Since the antennas had to be located where the best signal existed, it was necessary to preamplify the signal and relay it to the transmitter building through coaxial cable type *RG11/U*. As soon as the system was activated with the transmitter operating, a series of problems developed as the result of spurious outputs from the transmitter, channel 3, and the spurious responses of the receivers operating on channels 4–10 and 12. By straightforward interference elimination (filters, etc.) these problems were eliminated. It was most difficult to remove the intermodulation components radiated from the transmitter, but it was done. Due to the greater median field intensity at the transmitter site, it was possible to reduce the antenna arrays to a simple stack 10-element yagi array for each channel.

After 4 years' experience with this arrangement, several factors appear as significant:

1. Mode of propagation is diffraction over the mountain obstructing the path. This is true even though the mountain ranges are heavily wooded.
2. Signal quality is excellent, with very little variation about the median value.
3. Signal quality necessary for retransmission must be much higher than that for CATV work, as the equipment differentiates the leading edges of pulses for clamping pulses. Poor transient response will render such equipment unusable.
4. Spurious responses of receivers are extremely difficult to cope with. It is better to use crystal-controlled converters and operate the receivers on a channel free of such spurious components.
5. Circuit reliability is as good as 99.95% on a yearly cumulative basis. Only difficulty occurs momentarily with "sporodic *E*."
6. Antenna siting should be done with the same care as with a less elevated location. The same gains can be realized.

No analysis has been made in depth to determine the type of distortions present for use with color (National Television Systems Committee standard). A preliminary observation indicates that, superficially, these circuits are usable for color. Investigation has been under way for some time to specify the exact nature of the distortions, if any, that exist in the transmission path.

Conclusions

The data and experience presented in this paper have shown the practicality of using long-distance "diffraction" fields for CATV and television broadcast use. The significant factors surrounding the use of such fields are as follows:

1. Local investigation of terrain effects is necessary to obtain optimum antenna siting.

2. Antenna gain should take place in the smallest possible physical volume practical, and with minimum height of array.

3. Reliability of such signals is excellent.

4. More research needs to be done to determine exact nature of transmission-path distortion for color. It may be acceptable as it is.

For those in the propagation field, a listing of circuit transmission losses is given in Table I.

THERE are four large-scale digital computers at Westinghouse Electric Corporation employed in making engineering calculations: one International Business Machine Corporation (IBM) *705* and three IBM *704*'s (Table I). This paper summarizes the experience with automatic coding systems at these four installations.

Analytical Department

The Analytical Department located at the East Pittsburgh, Pa., Works has an IBM *704* digital computer with a 8,192-word main core storage, 8,192 words of drum storage, and eight magnetic tape units. A peripheral tape-to-printer unit, card-handling equipment, and key punches are also available.

Most of the programs written for this machine are used to solve engineering problems for the Large Rotating Apparatus Department, the Industry Engineering Department, Atomic Power Department, Kansas City, Kans., Works (aviation gas turbines), Lima, Ohio, Works (small motors), South Philadelphia, Pa., Works (steam turbines), and for various Westinghouse customers such as electrical utility companies. A small amount of data processing and engineering problems from other sources is also handled.

Most of the Analytical Department programs, once written, have a rather short life, the charges for production on a job frequently being less than the program development cost. An obvious conclusion is that the ease of writing and debugging a program are far more important to an installation with this load characteristic than the efficiency of the final program.

There is a staff equivalent to 50 full-time programers generating programs at this installation. The work of this staff results in an average of 150 hours of billed computer time per month with a breakdown of 100 hours to prepare and test programs and 50 hours production on completed jobs. The majority of those who make up this staff of 50 are professional programers, although about 16% of the work is produced by casual programers working on an open-shop basis using the FORTRAN automatic coding system. A breakdown of the remaining 84% shows that 10% is coded using FORTRAN and 84% using the symbolic assembly program (SAP).

A sample of six programs written using the FORTRAN system was analyzed to determine the cost of preparation with the results compared to cost estimates for the same programs using the SAP system. The estimates of man-hours required using SAP were made on a basis of factors which have been extensively used in estimating costs in the department. Once the number of man-hours was reached, the estimate of machine time required for program assembly and debugging was made by using a ratio of 2 machine-hours per man-month. Of the six programs in the sample, three were calculations easily coded by FORTRAN for an 8,192-word *704*. These three were written by a full-time programer with previous experience using FORTRAN. Another was written jointly by a full-time programer and a design engineer with little FORTRAN experience. The last two of the sample were written by men with little previous experience in FORTRAN. One of these samples presented the further complication that the desired result could not be completely accomplished with FORTRAN and required modifications in the finished machine language program.

The following lists the results of the analysis. None of the production on the jobs is included in these figures; all time listed was spent in generating and testing the program.

	Man-Hours	Machine-Hours
FORTRAN (actual)	883	15.8
SAP (estimate)	2,541	28.9

Since these programs were produced, a new version of the compiler has been made available. This system, a modified version of FORTRAN II, has resulted in a minimum savings of 30% in compiling time, with cases on record of 50% savings. Figures available from accounting records of the department indicate that of the 15.8 machine-hours, 7.6 were consumed by the compiling process. Applying the 30% savings to this amount of machine time, a new table was constructed as follows:

	Man-Hours	Machine-Hours
FORTRAN (modified)	883	13.5
SAP (estimate)	2,541	28.9

It can be seen that an estimated savings of 63.2% in man-hours (elapsed time if it is assumed that one man did all the work) and 53.3% in machine-hours could be realized by using the FORTRAN system. From available published figures, representative costing rates per *704* hour

Paper 59-641, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., May 19–21, 1959. Manuscript submitted February 19, 1959; made available for printing April 29, 1959.

J. T. CARLETON and T. W. MARTIN are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.; N. CHACKAN is with the Westinghouse Electric Corporation, Sharon, Pa.

Table I. Large-Scale Digital Computers Used for Engineering Calculations

Location	Computer	Type of Work	Engineering Usage, Shifts	Production Time, Hours per Month per Programer	Program Testing Time, Hours per Month per Programer	Cost Ratio, Preparation to Production
Analytical Department, East Pittsburgh, Pa.	IBM 704	Service Bureau	1+	1	2	5
Air Arm and Electronics Divisions, Baltimore, Md.	IBM 704	Military systems performance and design calculation	1+	5	3	2
Atomic Power Division, Pittsburgh, Pa.	IBM 704	Atomic plant performance calculation	4+	30	$3^1/_2$	1/5
Transformer Division, Sharon, Pa.	IBM 705	Transformer design data processing	0.4	3	6	4

and per programer hour were determined. Using these rates, the cost of generating the programs using FORTRAN would be $13,555 compared with an estimated cost using SAP of $35,525. This represents an estimated savings of 61.9% in the preparation cost of the jobs.

These figures were applied to the load of the Analytical Department computer with the following assumptions:

1. Fifty per cent of the work of the department is either unsuitable for FORTRAN coding or is already being accomplished in FORTRAN. This assumption implies that 24% of the work is unsuitable for FORTRAN since 26% is being written using that system as pointed out previously.
2. The remaining 50% is such that the 2-to-1 ratio between debugging hours and production hours still holds.
3. A program resulting from FORTRAN is 20% less efficient than one generated by a skilled programmer using SAP. This appears from experience to be a more-than-generous allowance for the inefficiencies of a FORTRAN program. It also could be pointed out that careful coding is necessary to produce an optimum SAP program and would thus increase the number of man-hours required to produce the final program.

Table II represents the effect of applying the figures from the foregoing tables.

It will be noted that this results in a decrease of 21.65 machine-hours billed to customers per month; so in evaluating the cost savings, a machine overtime rental rate per *704* hour will be used. Using this figure, the same amount of work could be accomplished with a staff of 15 fewer programers and at a savings of 21% present total expenses.

FORTRAN SERVICE

To broaden the base of computer usage and to "computer-orient" the man with the problem, a FORTRAN Service has been inaugurated. The compiler was simplified by prohibiting the use of the more sophisticated statements which experience indicated were common sources of programing errors. Reference material in the form of a FORTRAN service manual (summarized in Fig. 1) and a 2-hour course of instruction were arranged. These, together with occasional assistance from a FORTRAN Service Group, have been all that is necessary to make the power of the IBM *704* available to the engineer with the problem. Preparation of the cards, operation of the computer, and other details are handled by the FORTRAN Service Group so that the user need have no knowledge of computer operating procedure.

More than 200 engineers in the East Pittsburgh area attended the 2 hours of instruction. Subsequently, a survey was made which yielded the following results:

1. Twenty-two per cent of those attending wrote programs.
2. Of those who wrote programs, one-third did not attempt to compile. Of the remaining two-thirds, all produced useful programs.
3. All those interviewed felt capable of programing a simple problem.

Perhaps the most significant development resulting from the introduction of the FORTRAN Service has been the development of a number of extremely competent programers from among our engineers. After mastering simplified FORTRAN, many have proceeded on their own initiative to use the more sophisticated statements to the extent that they now have at their disposal the full capability of the *704* and FORTRAN.

Air Arm, Electronics Divisions

The IBM *704* at Air Arm Division, Baltimore, Md., jointly used by Air Arm and Electronics Divisions, has a main core storage of 8,192 words, drum storage of 8,192 words, eight tape units, and peripheral equipment. Its principal use is in the determination of military systems performance, detailed design of electronic components, and reduction of flight test data. Programs once written have a moderate life, with the production running time slightly greater than the program writing and testing time.

Table II. Application of Modified Fortran Figures

	Machine, Production Hours	Machine, Debugging Hours	Programer Hours, 176 Hours Per Man-Month
Present time	50	100	8,800
Estimated change	+ 5	−26.65	−2,781
Result	55	73.35	6,019

This computer was placed in operation in October 1957, coincident with the availability of FORTRAN. Although the personnel had had considerable experience with SAP on the Analytical department machine, FORTRAN was almost immediately adopted. By December 1957 the bulk of the programing was done in FORTRAN, and at present approximately two-thirds of the programing effort is in FORTRAN.

Several changes in FORTRAN were made, including:

1. A binary tape loader.
2. Print-out of octal instruction locations to facilitate making corrections and modifications.
3. Expansion of library routines to include Bessel functions, solution of simultaneous equations, and solution of nonlinear simultaneous differential equations.

This installation has not made a detailed comparison of conventional programing methods with automatic programing techniques; however, these facts are significant.

Prior to the installation of this computer, a study was made of IBM *704* facilities doing similar work. This study indicated that 40 programers would be required for one shift operation. Using FORTRAN, only 25 programers have been required.

The solution of a 25th order nonlinear differential equation was required to study an air-to-air missile. Five programers required 6 months to get a working program using SAP. Using FORTRAN

When in Doubt Use Parentheses ( ).

GENERAL INFORMATION

1. The name of a variable must not begin with I,J,K,L,M,N or a number.
2. Statement numbers are written in any column from 1 through 5. A statement number can be any number between 1 and 9999. They do not have to be in order.
3. When using C for comments, C is always written in Column 1. A line with C in column 1 will be ignored by Fortran.
4. If a statement is too long to fit on a single line it can be continued over as many as 9 additional lines. Continuation lines must be numbered consecutively from 1 to 9 in Column 6.
5. Arithmetic operations are performed in the following order: Exponentiation, Multiplication and Division, Addition and Subtraction. Operations are performed from left to right.

Fig. 1. Simplified FORTRAN summary

and the Integration with Controlled Error Library Routine, two programers were able to get a similar program working in 6 weeks. Although learning should be credited with part of this reduction, the use of FORTRAN was certainly the dominant factor.

Atomic Power Division

The Atomic Power Division has an IBM *704* with main core storage of 32,768 words, magnetic drum, tapes, and peripheral equipment.

Most of the programs run on this machine involve the solution of partial differential equations associated with calculating atomic power plant performance. The programs are general in nature and, once written, are widely used over an extended period of time. Only 10% of the computer time is used for writing and testing programs.

Because of a large dollar expenditure in production (in excess of four shifts), the running time is of prime importance. Therefore the bulk of the programing is in SAP, very little FORTRAN being used.

Transformer Division

Transformer Division's IBM *705* is used for data processing and engineering. The main frame has a storage capacity of 40,000 digits with auxiliary drum storage of 60,000 additional digits. Ten tape units are connected to the computer in addition to a printer, card punch and card reader. Peripheral equipment consists of two tape-to-printer units. A key punch is located in the main computer room for instant accessibility to computer users.

Transformer Division's major engineering problem is the design of transformers. This is divided into three basic groups; design of shell-form transformers 12,000 kva and up, design of core-form transformers, and design of reactors. Each design problem is treated separately and independently of the others. The computer solutions to these and other engineering problems require the full-time effort of five engineers plus approximately five nonengineers. Since the main memory is insufficient for long detailed programs such as transformer design, these programs are subdivided into many parts each of which is located on tape or drum and called in when needed. Thus, a program is capable of an unlimited number of instructions. Results of calculations are stored in memory, on tape, and on drum. Electrical and design specification data and forms are prepared on tapes for peripheral printout.

The computer operates two 8-hour shifts. Of this total, approximately 20% is devoted to the Engineering Department. At present the total engineering time is approximately 65% debugging, 35% production.

Conclusions

Automatic programing methods such as FORTRAN provide a powerful tool in the hands of experienced programers and will play a major economic role at installations where the cost of writing and checking programs is equal to or greater than the production cost.

A simplified version of FORTRAN supported by a service organization to handle the mechanics of operation and scheduling is an excellent method for making the facilities of the *704* available to a large number of engineers. It also provides an inexpensive and effective method of training engineers to become competent programers.

The ease of programing provided by FORTRAN allows more attention to be focused on the analysis of the problem. Improvements made by users have further increased the usefulness of FORTRAN by allowing the programer's orientation to turn even more to the problem where it belongs.

Compilers require that the computer be used to prepare the final program; however, the extra computer time is recovered with interest by a reduction in errors and a consequential decrease in computer time during the debugging phase.

The use of compilers is not restricted to large-scale computers. Small- and medium-scale computers may be effectively used for problems that are easily contained in their memory.

Appendix I. Description of Coding Systems

IBM 704

The *704* is a stored-program digital computer, i.e., an entry in the computer may be either an instruction or a number. To complicate matters, the machine uses the binary number system, a system not always easily converted from the usual decimal system. A typical instruction is CLA, clear and add, which results in clearing the accumulator and inserting the contents of a specified core storage unit. The binary code for CLA 7 is

000101000000000000000000000000000111.

An example of a number in the floating binary system is the representation of 1:

010000001100000000000000000000000000.

Other instructions or numbers are coded as different combinations of the so-called binary bits.

It is obvious that a method easier than hand coding in machine language had to be developed in order to make good use of the computer. Two such systems have been produced, SAP and FORTRAN. The SAP is a translator of symbolically coded instructions or numbers into machine language. An example might be a program to compute the circumference of a circle knowing that the radius is given at a specific location *R*. The following code when translated by SAP will produce a program which will accomplish the calculation.

```
START LDQ R       PLACE RADIUS IN MULTI-
                    PLIER-QUOTIENT REG-
                    ISTER
      FMP 2.      MULTIPLY BY 2
      STO TEMP    STORE RESULT TEMPO-
                    RARILY
      LDQ TEMP    PLACE 2R IN MULTIPLIER-
                    QUOTIENT REGISTER
      FMP PI      MULTIPLY BY π
      STO CIRC    STORE ANSWER IN CIR-
                    CUMFERENCE
      HTR         END OF CALCULATION
R                 LOCATION OF RADIUS
2.    DEC 2.
TEMP              TEMPORARY STORAGE
PI    DEC 3.1416
CIRC              LOCATION OF RESULT
      END START   END OF PROGRAM. START
                    COMPUTING WITH
                    START
```

The program causes the radius *R* to be multiplied by 2, this product to be multiplied by π, and the final result stored in CIRC. The HTR causes the computer to stop. Notice that every symbolic location must be specified in the program. A complication arises when it is desired to read in the value of the radius and print out the value of the answer. The procedure is made somewhat easier than might be expected by the use of prewritten subroutines from a library file. Other library subroutines are available such as square root, natural log, and trigonometric functions.

Another sophistication which can be included in SAP is the use of interpretive subroutines. Interpretive programing allows a programer to call for instructions which do not exist for the machine but which are translated and accomplished by the subroutines. An example of this type of programing might be the use of complex number arithmetic which the *704* cannot do directly.

The latest step towards ease of programing is the compiler, for example, FORTRAN. The compiler is a computer program which will translate a language close to English and algebra into machine language. The compiler accepts statements in the language and organizes them into a symbolic program that is fairly well optimized and which can be translated by SAP into a machine language program. To accomplish the computation of the diameter given the radius of the circle as before, one would write:

```
CIRC=2. *3.1416 *R
STOP
```

The compiler would then take over all the functions of translating into machine language and assigning all storage locations necessary. A complete program for this purpose including input and output would be

```
READ   R
CIRC  =2. *3.1416 *R
PRINT  CIRC
STOP
```

The use of the compiler can accomplish large savings in time and manpower as dramatized by the example of six FORTRAN programs. An added advantage is the ease of training programers. The engineer needs to know only the 32 types of statements of the compiler; and, in fact, he can do a great deal of programing with far fewer than the 32.

IBM 705

The *705* is similar to the *704* in that it, too, is a stored program machine. The major difference is that the *705* is a variable-length field machine using a decimal number system. The *705* is therefore more suitable to data processing where restrictions to fixed word lengths would create additional programing problems and an unjustifiable use of memory. Lengths of fields in the *705* are defined by signed fields and proper use of instructions.

A single machine instruction or program step for the *705* consists of five digits broken into two separate parts.

1. Operation part: alphabet or numeric high-order character which designates the operation to be performed.
2. Address portion: last four digits which is the address of some position in memory or some input-output device.

Occasionally a problem is programed directly in machine language thus bypassing the intermediate steps necessary to convert an automatic code to this language. To do so requires thorough knowledge of the computer plus programing care since zoning above every digit is extremely important, affecting constants as well as the instructions themselves. For relatively short problems, however, machine language may be desirable since it eliminates the assembly process.

Practically all of the Transformer Division's programs are written in symbolic language, a language that substitutes a 5-digit numeric address for an actual machine address and a 2- or 3-digit alphabetic code for the machine instruction. It is unnecessary for the programer to keep track of memory locations. He is required to specify the initial address location only if the program is to be located at some fixed place.

The *705* symbolic programing procedure does not reduce the number of instructions for a given problem. After a problem is programed in symbolic language, an assembly program converts the symbolic addresses to actual machine addresses, changes the symbolic instructions to single characters, and positions the proper zoning to identify the various accumulators and memory quadrants. As a final stage, 13 machine instructions are condensed and punched onto one 80-column card.

Another form of coding which has been used for a limited number of engineering problems is the Print I (pre-edited interpretive) routine. This is an automatic coding system of the interpretive type, the major portion of the coding and clerical work being done by the computer itself. A program consists of Print I and/or *705* symbolic instructions designed to bring in data, do arithmetic and logical operations, and produce output. After these instructions are punched on cards, the pre-edit routine of the Print I system will process the program cards and convert them to pseudo-instructions. Print I is not suitable

Table III. Basic Machine Language

Actual Location	Machine Instruction
1104	B 0004
1109	8 2013
1114	7 1169
1119	8 2021
1124	7 1179

1224	H 2629
1229	8 12$\bar{2}$9
1234	Q 28$\mathring{3}$9
1239	1 0304
1244	F 2849
etc.	

for data processing. For short engineering problems where alphabetic data are not needed or unimportant, Print I has proved to be acceptable. A comparison between the symbolic and Print I systems will yield approximately a 30 or 40 to 1 ratio, 30 to 40 symbolic instructions to one print instruction. However, since the executive routine must always be used to interpret the pseudo-instructions, actual running time of Print I is always more than that of machine language, averaging approximately 12% more.

The present-day automatic coding system used at Transformer Division is AutoCode. This is similar to Print I except that it is a compiling system rather than an interpretive system. It is far more flexible and adapts readily to data processing.

Appendix II. Comparison of Coding Systems

As an example of the various coding systems, the following problem was coded in *705* machine language, Symbolic, Print I, FORTRAN, and in the APS III compiler. Symbolic and Print I apply to the *705*. The FORTRAN problem was run on the *704*, and the Datatron *205* was used with APS III.

Problem:

To calculate the horizontal component of flux as a function of current in a conductor and as a function of the parameters w, t, h, and k where

t = thickness of a conductor of rectangular cross section

w = width of conductor of rectangular cross section

h, k = horizontal and vertical co-ordinates of a point in the plane of the cross section

Formula:

$$\frac{wH_x}{0.2I}=1/2\left(A\ln\frac{A^2+C^2}{A^2+D^2}+B\ln\frac{B^2+D^2}{B^2+C^2}\right)+D\left(\tan^{-1}\frac{B}{D}-\tan^{-1}\frac{A}{D}\right)+C\left(\tan^{-1}\frac{A}{C}-\tan^{-1}\frac{B}{C}\right)$$

Where:

$$A=\frac{h}{t}-\frac{w}{2t},\quad B=\frac{h}{t}+\frac{w}{2t},\quad C=\frac{k}{t}-1/2,\quad D=\frac{k}{t}+1/2$$

705 Basic Machine Language and Symbolic Coding

For the *705* computer 213 instructions, 34 constants, 20 work-area regions, and a print-out area were necessary in addition to the floating point subroutines. For the floating point subroutines the maximum total number of executable instructions is 2,035, depending on what particular paths in the subroutine are taken. Programing time was 2 days; assembly time, 6 minutes; and debugging time, 1 day. This does not include time required for punching cards and the interim time between any of the various phases.

Input variables were changed automatically by the program for a large number of points. Reloading time, therefore, for additional points was nonexistent. Initial load from card reader required approximately 25 seconds. A total of 353 calculations were performed in approximately 5 minutes, each calculation having approximately 2,000 instructions plus change of variables.

Tables III and IV give the first 24 instructions of this problem in machine language and in symbolic language. The foregoing discussion applies to both methods except that no assembly time is necessary for machine language. Note that for machine language no description can be given on the cards.

Print I

Sixty-six total instructions were required in print language. The first 20 of these are shown in Table V. Running time was approximately 10% greater than machine language. Programing time was 1 day, assembly time (pre-edit), approximately 5 minutes.

Fortran

This same problem was programed for the *704* computer. The entire program is listed in the following, a total of 20 instruction statements plus eight format and dimension statements. Programing time was less than 10 minutes, excluding setting up the equations. Conversion of statements into machine language, resulted in 290 instructions, excluding subroutines. Running time for a problem of 1,008 points was 6 minutes distributed as follows:

Set up and lost motion	1–20
Compiling	2–50
Load program	0–20

APS III

Programing was done in a symbolic language acceptable to the APS III compiler system for the Datatron *205* as developed by Dr. H. G. Rice, Westinghouse Research Laboratory. The APS III compiler system is similar to the FORTRAN system in that it utilizes a mathematical notation requiring the programer to know very little about the operation of the computer.

Approximately one hour was required to write this problem in compiler language. The total program consisted of 32 lines. No special forms were required for programing, any available paper being satisfactory. The complete program is shown in the following. Upper-case letters in formulas refer to arithmetic and mathematic operations such as sum difference, product, quotient, arctangent, etc. Lower-case letters represent the names of variables.

```

```

The previous instructions or statements are in the compiler language. The compiling routine transformed these 32 lines or statements into 143 machine language instructions (plus 337 instructions for subroutines), the first ten of which are as follows. This, incidentally, is how the program would have to be programed in machine language.

```

```

Compiling and punching the input paper tape required approximately 11 minutes' time. Input to the computer must initially be from paper tape; however, programs could be accumulated on magnetic tape and read into memory similar to the magnetic tape system of the IBM *700* series computers.

The limiting factor for running this problem on the Datatron computer is the typewriter if it is used as output. To illustrate, the magnetic field problem was run both with and without the typewriter. Running time for the problem was 124 seconds for 12 points or 10.3 seconds per point with the typewriter as output. Elimination of typewriter in favor of tape output required 72 seconds for 12 points or 6 seconds per point.

Summarizing, the magnetic field problem required the following approximate times using APS III:

Programing of problem, 1/2 to 1 hour.
Compilation and punching of input tape, 10 minutes.
Running time, 1 minute plus 6 seconds per point.

Comparisons

If actual running time of problem only is considered, the following is an approximate comparison of speed of the various computers for calculation of one point of the magnetic field problem.

IBM *704*, 0.085 second per point
IBM *705*, 0.85 second per point
Datatron *205*, 6 seconds per point

However, the most logical comparison involves cost of program preparation as well as running cost. The superiority of the compilers is shown by Table VI.

◆

Discussion

A. E. Peterson (Bell Telephone Laboratories, Inc., Whippany, N. J.): The authors have accomplished much in pointing out the usefulness of automatic coding systems such as FORTRAN. FORTRAN is a mathematical formula translating system for the IBM *704* computer. As cited in Appendix I, FORTRAN is written in a language close to English and algebra. This feature considerably reduces programing complexities for the noncareer programer, therefore making it attractive to people such as engineers.

It is felt that many readers would do well to read the appendixes first, since they contain a wealth of general information on the subject. Appendix I gives a good general description of several coding systems, including FORTRAN and SAP. Appendix II gives a comparison between four systems, which is nicely summarized in Table I showing cost comparisons. The advantages of automatic coding systems are quite obvious from this table.

I have written programs in both symbolic and automatic coding systems. The automatic system (FORTRAN) was considerably easier to use than the symbolic. A specific instance taken from my memory was a program for floating-point addition. This program, when written in symbolic language, required more than 20 steps, but with FORTRAN, only several statements were necessary.

A Study of Thermal Deterioration of Kraft Pulps Using a Mass Spectrometer

Y. SAITO
MEMBER AIEE

T. HINO
NONMEMBER AIEE

AS THERMAL deterioration of electrical insulating materials is directly connected with their lives it has been an important problem since electric machines and apparatuses were put to practical use. Nevertheless, a thorough study has not been made on the subject because quite a long time is required for testing the lives of the materials and also because numberless combinations and many working conditions of materials must be considered in order to get sufficient data concerning the problem. Moreover new insulating materials are rapidly appearing and it has become necessary for us to know their deterioration properties. Consequently, it is necessary to find a test method which will enable us to know these characteristics within a short period of time. Accordingly the authors intended to find the degradation of some kind of insulating materials with a mass spectrometer as it was impossible to detect a large quantity of deterioration products by the apparatus in general use.[1] Kraft pulps were taken as samples first. In analyzing thermally generated gases from the samples, fundamental data were obtained in a short time by which thermal endurance of the materials could be concluded.

Measurement of Thermal Deterioration with Mass Spectrometer

MASS SPECTROMETER

The mass spectrometer employed in the research was an *RM-A* type manufactured by Hitachi Electric Company. It has a 90-degree type of analyzer tube and a gas container that will hold 10 liters.

SAMPLES

Kraft pulps was taken as samples for the investigation. The pulps having different degrees of beating were prepared. The properties of the samples are summarized in Table I. All samples in the table are of the same origin; the second column shows the degree of beating measured with Schopper-Riegler's apparatus. The "Measurement on Thermal Deterioration" section aims to show how the effect of a slight difference in the treatment of the sample can be detected with a mass spectrometer.

PRETREATMENT OF SAMPLES

Fibrous materials which have lain in open air for a long time have absorbed a considerable amount of water. Consequently all such samples have to be thoroughly dried in a vacuum vessel to expel the moisture in order to get equal initial conditions for all measurements. Kraft pulp is treated in a vacuum vessel at 50 C (degrees centigrade) for 4 hours.

MEASUREMENT OF THERMAL DETERIORATION

A glass flask arrangement, shown in Fig. 1, is used in order to gather the gas driven out from a sample. *A* and *B* are glass flasks, each having a capacity of 300 cc (cubic centimeters). A sample is inserted in *B*. After the flask arrangement has been evacuated and filled with some sort of gas, *B* is heated to a prescribed temperature. Then some of the gas or vapor is produced in *B* and half of the quantity is put into *A*. These processes are all realized by the proper operation of three glass cocks, C_1, C_2, C_3, in Fig. 1 and by a vacuum pump or source of gas which is not seen in the figure. After this *A* is separated from the whole glass arrangement at *F* by fusion. *A* has a double seal by which the gas in *A* is transferred into the glass container of the mass spectrometer by connecting *A* to it and breaking the inner seal. When a sample is to be heated in oxygen or argon a liquid air trap is used to separate the produced gas from these gases. *M* is a McLeod gage and *P* is the connection to the vacuum set. Total pressure of generated gas is measured by *M*, and sometimes it is necessary to correct the indication of *M* when too much water vapor is generated.

AN EXAMPLE OF ANALYSIS

Fig. 2 shows an example of a spectrogram of a sample of Kraft pulp drawn by the mass spectrometer. Table II is the result calculated from the peak values in Fig. 2. The second column of the table shows the height of every peak in Fig. 2 and the third column is the relative value of each gas expressed in molecular per cent compared to H_2O. The result is obtained by heating 10 gm (grams) of Kraft pulp for 4 hours at 135 C. It is clear from the table that H_2O, CO_2, and CO are the main products decomposed from the pulp.

EXPERIMENTAL RESULTS

In each case 10 gm of pulp is used for the following experiments. The result of analysis is given by the pressure of each gas in millimeter (mm) Hg (mercury) in a 1-liter vessel at 0 C, and is generated for 1 hour at each step of temperature. As it is considered reasonable to observe carbon atom in order to know the decomposition of cellulose, CO and CO_2 particularly are picked up.

CHANGE OF PRODUCED GAS WITH LAPSE OF TIME

The change of the quantity of thermally expelled gas from cellulose is examined after a lapse of time and after heating the sample at 135 C. Although the rate of the total gas generation is considerably large in the initial stage of heating it is gradually decreased and settles to a constant rate after prolonged heating. It is rather curious that H_2O does not seem to come out at the initial stage of heating, but is generated at nearly constant rate after some time has elapsed. The ratio between CO and CO_2 fluctuates during the initial period of heating, but it becomes a nearly constant value in from 20–30 hours.

Table I. Properties of Kraft Pulps

Sample*	Degree of Beating	Potassium Permanganate Number	α-Cellulose Content, % More Than	Resin Content, % Less Than	Ash Content, % Less Than
No. 1	Unbeaten	28	85	0.3	1.0
No. 2	58				
No. 3	85				

* The three samples are of the same origin but different in degree of beating.

Paper 59-116, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted July 22, 1958; made available for printing April 1, 1959.

Y. SAITO and T. HINO are with The Tokyo Institute of Technology, Tokyo, Japan.

Thermal Properties of Kraft Pulp Having Different Degrees of Beating

Fig. 3 compares thermal endurance of samples *1*, *2*, and *3* in Table I. The pretreatment of the samples is continued for 30 hours at 135 C. The abscissa is the reciprocal of treating temperature *T*, and the ordinate is a logarithm of adjusted pressure of $CO+CO_2$ produced from the samples. In Fig. 3 *a*, *b*, *c*, show the relation in oxygen having a pressure of 150 mm Hg; *a'*, *b'*, *c'* are the relations in vacuum, and *a"*, *b"*, *c"* are the relations in argon having 1 atmospheric pressure. All the relations show straight lines having a slight difference in height and inclination, consecutively varied with the change of degree of beating.

Effect of Atmosphere on Thermal Decomposition

Although the difference of thermal deterioration of three samples of Kraft pulp in O_2, vacuum, and argon have been shown in Fig. 3, the properties of sample *1* in oxygen, vacuum, and argon are pointed out again in Fig. 4. For the purpose of pretreatment, the pulp is heated for 4 hours at 50 C. It is easily imaginable that a quantity of generated gas would be large and the ratio CO/CO_2 would be irregular at the beginning of heating even though such a degree of pretreatment has been applied. Nevertheless the relations between $\log P_{CO+CO_2}$ and $1/T$ are exact straight lines having nearly equal inclination as shown in Fig. 4. The quantities of generated gas differ remarkably from one another.

Effect of Beating on Thermal Deterioration

As many samples of Kraft pulp having different degrees of beating have been prepared besides those in Table I, their relation of gas generation and the degree of beating is measured at 115 C in oxygen, keeping the pressure at 150 mm Hg. It is shown in Fig. 5 that the volume of generated $CO+CO_2$ increases as the degree of beating grows stronger. This shows that the thermal deterioration of Kraft pulp is quickened by beating.

Although the change of physical and chemical properties accompanied by the beating has been ascertained already in various aspects,[3] change of the cellulose molecule itself does not seem to occur, i.e., the degree of polymerization, copper number, and the diffraction pattern of X ray do not seem to be altered by beating. Owing to the beating the most remarkable change seems to be that the pulp gets more slender, consequently the effective surface area of the pulp increases and the thermal deterioration is quickened.

Relation Between Mass-Spectrometer Method and Weighing Method

The mass-spectrometer method is compared with the weighing method to see if the data obtained in a short time by the former method are useable as well in judging long-time deterioration. Sample *1* is heated for a very long time at various temperatures arranged for the experiment and weighed every 24 hours to note the decrease of weight. Fig. 6 shows the relations between the time (in days) of heating and weight decrease (in per cent). Anomalous decrease of the weight at the initial stage of heating is not included in the figures. From the results indicated in Fig. 4(A) and those in Fig. 6, the relation in Fig. 7 is derived. This shows the rate of weight decrease of sample *1* pulp for 24 hours when it is heated at each stage of temperature. The three black spots in the figure are obtained actually by weighing method and the remaining points are calculated from the data obtained by mass spectrometer method. The upper limit of the rank of vertical short line shows the value when the oxygen in the generated gas (CO, CO_2) is assumed to have come out from the constituent of cellulose, and the lower limit shows the relation when all the oxygen in the generated gas is assumed to have come from the atmosphere. It can easily be seen from the figure that the straight line obtained by weighing method has nearly the same inclination as those obtained by the mass-spectrometer method and the quantity of generated gas measured by each method seems to coin-

cide approximately. (Better agreement was ascertained between the results obtained by both methods when samples were tested which had been heated for 20–30 hours at 135 C.) Thus it is possible to assume that the deterioration of the material over a long period of time can be forecasted by the short-time test with a mass spectrometer.

Discussion of Results

Effect of Moisture

The rate of generation of gases from pulp is very large at the initial stage of heating. This may be due to the still remaining moisture in the fibrous structure which causes the generation of a large quantity of $CO+CO_2$. In order to verify such an effect sample *1* is heated for a long time in vaccum at 135 C. When the gas generation has become constant the sample is sufficiently exposed to moisture. Then it is treated in vacuum at 50 C for 4 hours, as formerly mentioned, and heated in vacuum at 135 C again. It is found that the sample shows quite the same character in gas generation as at the first heating. The result is shown in Fig. 8. As the effect of moisture on gas generation from pulp is very serious, every precaution in examining the thermal deterioration of fibrous materials must be taken.

Relation Between $\Delta p \sim 1/T$

The logarithm of the volume of $CO+CO_2$ that is generated for a definite time by thermal decomposition of Kraft pulp has linear relation with the reciprocal of the temperature in absolute scale. This is derived from the theory on chemical reaction as originally carried out by Dakin.[8] The rate of chemical reaction is generally expressed by the following relation:

$$\frac{dc}{dt}=KC^n \quad K=-A\epsilon^{-E/RT} \tag{1}$$

where

C = concentration of material under reaction
E = activation energy
T = absolute temperature
t = time
R = gas constant
A, n = constant

Thermal decomposition of the Kraft pulp is considered as one of the cases represented by equation 1. As the time spent by the thermal decomposition in the present case is very short compared to the life of the material, concentration C is considered to be constant during the reaction. Then the following equation is derived from equation 1:

$$\frac{\Delta C}{C_0^n}=A(\epsilon^{-E/RT})\Delta t \tag{2}$$

where

C_0 = initial concentration
ΔC = decrease of concentration

as CO and CO_2 are generated when cellulose is decomposed, the pressure Δp of $CO+CO_2$ is thought proportional to ΔC, i.e.,

$$\Delta p=\alpha\Delta C \tag{3}$$

Inserting equation 3 in equation 2 and making use of logarithmic expression:

$$\log \Delta p=\log C_0^n+\log A+\log \alpha+\log \Delta t-\frac{E}{RT} \tag{4}$$

As C_0, A, Δt, and n are all constant, equation 4 can be simplified as follows:

$$\log \Delta p=C-\frac{B}{T} \tag{5}$$

where $B=E/R$ and C = a constant.

Equation 5 shows linear relation beween $\log \Delta p$ and $1/T$. This is the same form as the equation representing the relation between the life and the temperature of insulating materials derived first by Dakin and is approved if the generation of CO and CO_2 from the pulp is the main reaction which caused the change of

physical properties in accordance with thermal deterioration.

Effect of Degree of Beating

The effect of the degree of beating on the thermal deterioration of the Kraft pulp is shown clearly in Fig. 3. As the reciprocal of the rate of the disintegration is considered proportional to the life of the material, it is easily seen from Fig. 3 that the lives of pulp no. *1* and no. *3* in oxygen have the ratio of nearly 1-to-2.5 at 90 C. This fact shows that the thermal endurance of the samples is indeterminable even though the samples have the same origin. As to the straight lines in Fig. 3, their inclinations are distinguishable. The inclination is a little steeper in vacuum or in argon than in oxygen for the same sample. But the straight lines in vacuum and argon have nearly equal inclinations. The less the degree of beating of the sample, the steeper the inclination of the straight line in oxygen. Activation energy of the steepest straight line for sample *1* is 34.6 kilocalorie/molecule in vacuum and that of the least steep line for sample *3* is 24.5 kilocalorie/molecule in oxygen.

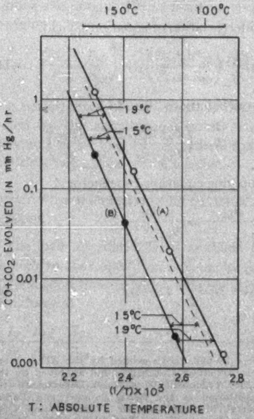

Fig. 9. Rate of gas generation in oxygen (A) compared with rate in vacuum (B), sample 1

Differences Due to Atmosphere

It is clearly understandable from Fig. 3 that the deterioration is promoted by the presence of oxygen as usually expected. The fact that the maximum temperature of class *A* insulating material is 15 C higher than that of class *Y* material is attributed to shutting off oxygen in the atmosphere from the fibrous material by coating it with varnish, oil, etc. Figs. 9(A) and (B) are the same as the straight lines in Fig. 3 and are approximately parallel to each other. From Fig. 9 it is easily seen that if the sample is tested in vacuum at a temperature 19 C higher than in this figure, the straight line expected will coincide with the line in oxygen. This means that if the oxygen atmosphere is thoroughly shut off from the sample and it is put in vacuum it can withstand higher temperature by 19 C than if it were in oxygen. The dotted line in Fig. 9 shows the characteristic at a temperature 15 C lower than the straight line. It corresponds to the state of class *Y* mentioned before.

Comparison of Results on Deterioration Tests

Fig. 10 is the comparison of our results with other authors' results. Figs. 10(A) and (B) are cited from Stewart's report[4] and show the decrease of breakdown voltage of Kraft papers by thermal deterioration in nitrogen and in air. Fig. 10(C) is quoted from Murphy's report[5] which shows the generation of CO+CO$_2$ from Kraft paper by heating. Fig. 10(D) is the result obtained by heating Kraft pulp in vacuum, reported in this paper. The ordinate shows the time required to produce unit volume of CO+CO$_2$ from the pulps at 0 C, 1 atmosphere. Fig. 10(E) is also obtained from the present test in oxygen and shows the same relation as (D). Fig. 10(A) and (C) have nearly equal inclination to the straight line (D)1. Fig. 10 (B) and the straight line (E)3 have nearly equal inclination.

Sensitivity of the Mass Spectrometer

A mass spectrometer enables us to analyze a material as mentioned before. The quartz spring balance we used has a loading capacity of 3 gm and the elongation for the change of the load by 1 gm is 67 mm which is read by a microscope having a magnifing power of 7, so the mass spectrometer is a few hundred times more sensitive than the spring balance. Thus the spectrometer enables us to detect the thermal deterioration of materials in a very short time and even at operating temperature.

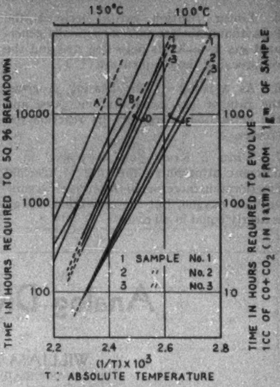

Fig. 10. Comparison of results obtained by different authors

C—Gas generation of Kraft paper, Murphy's data

D—Gas generation of Kraft pulps in vacuum, authors' results

E—Gas generation of Kraft pulps in oxygen, authors' results

Conclusions

The thermal deterioration of insulating materials is investigated with a mass spectrometer in order to ascertain the merit of the method on the one hand and to get the actual data on Kraft pulps on the other hand. The results obtained are summarized as follows.

1. A mass spectrometer can be effectively applied, for the purpose of detecting thermal deterioration, to those materials which generate such products as gas or vapor by heating. In such a case, thermal deterioration can be tested at working temperature and in a short time.
2. The life of the insulating materials can easily be derived from the aforementioned results.
3. The mechanism of thermal deterioration of insulating materials can be clarified through the temperature range starting from the working temperature and progressing to a considerably high temperature.
4. Applicability of the result obtained at higher temperature for the purpose of judging the life at working temperature is easily noticed from item *3*.

5. Linear relation exists between the logarithm of the pressure of thermally generated gas from Kraft pulp (log Δp) and the reciprocal of the temperature ($1/T$).

6. As a result of the beating progress, the rate of gas generation increases and the activation energy of the reaction decreases.

7. When a Kraft pulp is placed in a different atmosphere the rate of thermal deterioration increases in the order of argon–vacuum–oxygen, but the activation energy is nearly equal in all cases.

8. Water vapor hastens very much the thermal deterioration of the Kraft pulp.

9. Rate of thermal decomposition of unbeaten Kraft pulp in oxygen is equal to that in vacuum at a 19 C higher temperature.

Analog Division Circuit

WILLIAM McMURRAY
ASSOCIATE MEMBER AIEE

IN THE FIELD of automatic control, there is a need for simple and reliable devices which perform the operations of analog multiplication and division. This paper describes a circuit containing only magnetic cores and windings, which produces an alternating voltage output directly proportional to the quotient of two d-c input signals. The output is also directly proportional to the alternating voltage used for excitation, which thus may be employed as a multiplier input signal, otherwise a regulated a-c supply is required. Since the circuit contains no semiconductors and is relatively insensitive to changes in the properties of the magnetic cores, it is well-adapted to operation at elevated temperatures.

The circuit, Fig. 1, consists of two similar cross-field reactors A and B, input transformer T_X, output transformer T_L, excitation voltage e_X, d-c control sources $2I_1$ and $2I_2$ in series with impedances Z_1 and Z_2 respectively, and load impedance Z_L. Resistances R_1 and R_2 represent winding resistances. The nonsaturated condition of the transformers maintains equal division of the control currents between the parallel paths at every instant. The turns ratios of the transformers are assumed to be unity in the analysis. An alternative arrangement which eliminates the need for transformers is shown in Fig. 2. It is assumed that the dividend control turns are equal to the excitation turns, and the divisor control turns are equal to the load winding turns.

This circuit is reported in the literature[1] as a multiplying circuit producing an output proportional to the product I_1I_2. However, the conditions under which this action is obtained are not given. The present paper deals with the mode of operation which produces an output proportional to the quotient I_2/I_1, hereafter termed the division mode.

A "hollow doughnut" core shape, Fig. 3, is suitable for construction of the cross-field reactors. A circular winding is inserted in the annular window, and a toroidal winding is put on after assembling the two halves of the core. The magnetic intensity produced by one winding is perpendicular to the magnetic intensity produced by the other winding, throughout the volume of the core. The location of the annular window is such as to maintain approximately uniform core cross-sectional area with respect to the annular winding.

Analysis

It is well known that the action of a cross-field reactor is a result of nonlinearity in the magnetization characteristic of the core. In a previous analysis,[2] this characteristic is expressed as a power series. Considerable simplification is achieved by assuming an isotropic core material having the magnetization characteristic of Fig. 4(A). When both of the mutually perpendicular windings on a core carry current, the magnetic flux density vector $\mathbf{B}_0$ is equal to B_S in the direction of the resultant magnetic intensity vector $\mathbf{H}_0$, see Fig. 4(B).

It follows that*

$$\frac{B_1}{H_1}=\frac{B_2}{H_2}=\frac{B_0}{H_0} \tag{1}$$

$$B_1^2+B_2^2=B_0^2 \tag{2}$$

where

$$B_0=B_S \tag{3}$$

DERIVATION OF GENERAL CIRCUIT EQUATIONS

The winding resistances are assumed to be negligible

$$R_1=R_2=0 \tag{4}$$

With sinusoidal voltage excitation

$$e_X=e_{2A}+e_{2B}=\sqrt{2}\,E_X \sin \omega t \tag{5}$$

$$N_2A_2\frac{d}{dt}(B_{2A}+B_{2B})=\sqrt{2}E_X \sin \omega t \tag{6}$$

Integration of equation 6 yields

$$\omega N_2A_2(B_{2A}+B_{2B})=-\sqrt{2}E_X \cos \omega t \tag{7}$$

Defining the per unit excitation as

$$b_2=\frac{E_X}{2E_{S2}}=\frac{E_X}{\sqrt{2}\omega N_2A_2B_S} \tag{8}$$

Equation 7 becomes

$$\frac{B_{2A}+B_{2B}}{B_S}=-2b_2 \cos \omega t \tag{9}$$

For the load or output circuit

$$e_L=e_{1A}-e_{1B}=N_1A_1\frac{d}{dt}(B_{1A}-B_{1B}) \tag{10}$$

Differentiation of equation 2 yields

$$B_1\frac{dB_1}{dt}+B_2\frac{dB_2}{dt}=0 \tag{11}$$

From equations 10 and 11

$$-e_L=N_1A_1\left(\frac{B_{2A}}{B_{1A}}\frac{dB_{2A}}{dt}-\frac{B_{2B}}{B_{1B}}\frac{dB_{2B}}{dt}\right) \tag{12}$$

Applying equation 1 to reactor A

$$\frac{B_{1A}}{\frac{N_1}{l_1}(I_1-i_L)}=\frac{B_{2H}}{\frac{N_2}{l_2}(i_X+I_2)} \tag{13}$$

$$a(i_X+I_2)=\frac{B_{2A}}{B_{1A}}(I_1-i_L) \tag{14}$$

---

where

$$a=\frac{N_2l_1}{N_1l_2}=\frac{N_2A_2}{N_1A_1} \tag{15}$$

since

$$A_1l_1=A_2l_2=\text{core volume} \tag{16}$$

Similarly, applying equation 1 to reactor B

$$a(i_X-I_2)=\frac{B_{2B}}{B_{1B}}(I_1+i_L) \tag{17}$$

Subtraction of equation 17 from equation 14 yields

$$2aI_2=I_1\left(\frac{B_{2A}}{B_{1A}}-\frac{B_{2B}}{B_{1B}}\right)-i_L\left(\frac{B_{2A}}{B_{1A}}+\frac{B_{2B}}{B_{1B}}\right) \tag{18}$$

The performance of the circuit is determined by the simultaneous solution of equations 9, 12, and 18. A general solution does not appear to be feasible.

Steady-State Operation in Division Mode

The load impedance Z_L is assumed to be high so that operation is close to the no-load condition, in which case equation 18 reduces to

$$2a\frac{I_2}{I_1}=\frac{B_{2A}}{B_{1A}}-\frac{B_{2B}}{B_{1B}} \tag{19}$$

If the d-c sources of I_1 and I_2 are steady, and the impedances Z_1 and Z_2 are large, I_2/I_1 is constant.

If it is also assumed that

$$/B_{2A}/\ll B_S \text{ and } /B_{2B}/\ll B_S \tag{20}$$

then

$$/B_{1A}/\approx/B_{1B}/\approx B_S \tag{21}$$

and equation 19 may be written approximately

$$2a\frac{I_2}{I_1}=\frac{B_{2A}-B_{2B}}{B_S} \tag{22}$$

from equations 9 and 22

$$\frac{B_{2A}}{B_S}=a\frac{I_2}{I_1}-b_2\cos\omega t \tag{23}$$

$$\frac{B_{2B}}{B_S}=-\frac{aI_2}{I_1}-b_2\cos\omega t \tag{24}$$

In view of equations 21, 23, and 24, equation 12 may be written approximately

Fig. 3. "Hollow doughnut" core of cross-field reactor

$$-\frac{e_{LO}}{N_1A_1B_S}=\frac{B_{2A}}{B_S}\frac{d}{dt}\left(\frac{B_{2A}}{B_S}\right)-\frac{B_{2B}}{B_S}\frac{d}{dt}\left(\frac{B_{2B}}{B_S}\right)$$

$$=\left(a\frac{I_2}{I_1}-b_2\cos\omega t\right)\omega b_2\sin\omega t+\left(a\frac{I_2}{I_1}+b_2\cos\omega t\right)\omega b_2\sin\omega t$$

$$=2a\frac{I_2}{I_1}\omega b_2\sin\omega t \tag{25}$$

$$e_{LO}=-\sqrt{2}\,E_{LO}\sin\omega t \tag{26}$$

where

$$E_{LO}=\sqrt{2}\,\omega N_1A_1B_Sab_2\frac{I_2}{I_1} \tag{27}$$

In view of equations 8 and 15, equation 27 reduces to

$$E_{LO}=\frac{I_2}{I_1}E_X \tag{28}$$

Thus the no-load output voltage is equal to the excitation voltage times the quotient of two control currents, and has the same frequency and waveshape as the excitation. (By inference, the latter conclusion also applies if the excitation is nonsinusoidal.) Note that E_{LO} is in-

dependent of the turns ratio N_1/N_2. Multiplication by a constant may be achieved by changing the turns ratio of one or both of the transformers in the circuit of Fig. 1, or between the corresponding reactor windings in the arrangement of Fig. 2.

For inequalities in equation 20 to be valid, it can be seen from equations 23 and 24 that the following restrictions must be met

$$b_2 << 1 \tag{29}$$

$$a\frac{|I_2|}{|I_1|} << 1 \tag{30}$$

Since no restrictions are placed on control current polarities, the circuit is a four-quadrant divider. Reversal of I_1 or I_2 (but not both) will reverse the phase of the load voltage.

The symmetry of the circuit is also noteworthy. If an excitation voltage $\mathbf{E}_X'$ is applied to the normal load terminals, a voltage E_{LO}' will appear at the normal excitation terminals, where

$$E_{LO}' = \frac{I_1}{I_2} E_X' \tag{31}$$

provided that now

$$a\frac{|I_2|}{|I_1|} >> 1 \tag{32}$$

The excitation current i_X may be obtained by addition of equations 14 and 17, which for the no-load condition results in

$$\begin{aligned} i_{XO} &= \frac{I_1}{2a}\left(\frac{B_{2A}}{B_{1A}} + \frac{B_{2B}}{B_{1B}}\right) \\ &\approx \frac{I_1}{2a}\left(\frac{B_{2A}+B_{2B}}{B_S}\right) \\ &= -\frac{I_1 b_2}{a}\cos\omega t \\ &= -\sqrt{2}\, I_{XO}\cos\omega t \end{aligned} \tag{33}$$

where

$$I_{XO} = \frac{I_1 E_X}{2\sqrt{2}a\, E_{S2}} \tag{34}$$

The voltage e_{C1} appearing across the divisor control circuit impedance Z_1 is given by

$$e_{C1} = \frac{1}{2}(e_{1A} + e_{1B}) \tag{35}$$

Through similarity with the derivation of equation 25 from equation 10

$$\begin{aligned} -\frac{2e_{C1}}{N_1A_1B_S} &\approx \frac{B_{2A}}{B_S}\frac{d}{dt}\left(\frac{B_{2A}}{B_S}\right) + \frac{B_{2B}}{B_S}\frac{d}{dt}\left(\frac{B_{2B}}{B_S}\right) \\ &= -2b_2\cos\omega t \times \omega b_2 \sin\omega t \\ &= -\omega b_2^2 \sin 2\omega t \end{aligned} \tag{36}$$

$$e_{C1} = \sqrt{2}\, E_{C1}\sin 2\,\omega t \tag{37}$$

where

$$E_{C1} = \frac{E_X^2}{8aE_{S2}} \tag{38}$$

Thus it appears that Z_1 should be large enough to effectively block the flow of second harmonic current caused by e_{C1}.

$$\frac{E_{C1}}{Z_1} << 2I_1 \tag{39}$$

The voltage e_{C2} developed across the dividend control circuit impedance Z_2 is

$$e_{C2} = \frac{1}{2}(e_{2A} - e_{2B}) \tag{40}$$

$$\frac{2e_{C2}}{N_2A_2B_S} = \frac{d}{dt}\left(\frac{B_{2A}-B_{2B}}{B_S}\right) \approx 0 \tag{41}$$

Hence it should be possible for Z_2 to be a comparatively low impedance without changing the mode of operation of the circuit.

TRANSIENT RESPONSE TO CHANGE IN DIVIDEND CONTROL SIGNAL

Suppose that I_2 changes with time, I_1 remaining constant. In view of equation 22, equation 41 becomes

$$\frac{2e_{C2}}{N_2A_2B_S} = \frac{2a}{I_1}\frac{dI_2}{dt} \tag{42}$$

Thus the dividend control circuit exhibits inductance. In the circuit arrangement of Fig. 1

$$L_2 = \frac{N_2A_2B_S a}{2I_1} \tag{43}$$

For the circuit arrangement of Fig. 2, the inductance is four times the value of equation 43.

The total dividend control circuit resistance (in Fig. 1 when Z_2 is a resistance) is

$2I_1=0.32$ amp

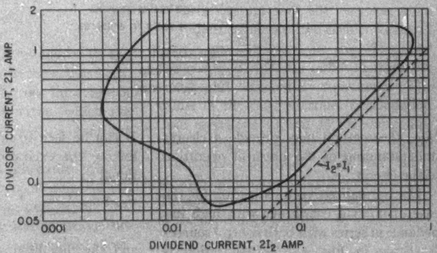

Fig. 12. Region within which $2I_1$ and $2I_2$ must be for $0.8<k<0.9$, when $E_X=16$ volts

$$R_{C2}=\frac{1}{2}R_2+Z_2 \qquad (44)$$

and the dividend control circuit time constant is

$$\tau_2=\frac{L_2}{R_{C2}} \qquad (45)$$

From equations 43 and 45 it is seen that the time of response to a change in dividend control voltage is inversely proportional to the divisor control current.

OPERATION OUTSIDE OF DIVISION MODE

A method of predicting the mode of operation when the restrictions of the division mode do not apply is to graphically relate the net magnetic flux linking the load circuit, the net fluxes linking the control circuits, and the exciting current with the net flux linking the excitation circuit. Since the latter flux is known from equation 9, the performance of the circuit may then be determined, though the complete process is rather tedious. The method is also applicable to the division mode and will aid in estimating the severity of the restrictions necessary to obtain a desired accuracy. In addi-

Voltage scales in volts

(A) $E_X=20$ volts; $2I_1=0.32$ amp; $2I_2=0.05$ amp
(B) $E_X=20$ volts; $2I_1=0.64$ amp; $2I_2=0.05$ amp
(C) $E_X=20$ volts; $2I_1=0.64$ amp; $2I_2=0.10$ amp

tion, the method may provide a clearer understanding of the physical operation of the circuit.

The normalized vector diagram for the case of no-load conditions with high impedance in series with both control sources is shown in Fig. 5. No restriction is placed upon the ratio I_2/I_1. If particular values of a I_2/I_1 and a i_X/I_1 are chosen, then the resultant flux density vector for reactor A makes an angle α with the B_1/B_S axis, where

$$\tan\alpha=a\frac{i_X}{I_1}+a\frac{I_2}{I_1} \qquad (46)$$

The resultant flux density vector for reactor B makes an angle β with the B_1/B_S axis where

$$\tan\beta=a\frac{i_X}{I_1}-a\frac{I_2}{I_1} \qquad (47)$$

It can be seen from Fig. 5 that the flux linking the excitation circuit is proportional to

$$\frac{B_{2A}+B_{2B}}{B_S}=\sin\alpha+\sin\beta \qquad (48)$$

and the flux linking the load circuit is proportional to

$$\frac{B_{1B}-B_{1A}}{B_S}=\cos\beta-\cos\alpha \qquad (49)$$

Equations 48 and 49 are related in Fig. 6, and ai_X/I_1 is related to equation 48 in Fig. 7; the parameter in both cases being aI_2/I_1.

It may be deduced from Fig. 6 that the load voltage will contain a third harmonic component of sufficient magnitude to cause the load voltage to be zero at six instants per cycle when the per unit excitation approaches unity. From Fig. 7 it can be seen that the excitation current approaches a rectangular waveshape of magnitude I_2 as aI_2/I_1 becomes large. In the limit, when I_1 is zero, the circuit reduces to the ordinary series saturable reactor with high control circuit impedance.[3]

Experimental Verification

The circuit arrangement of Fig. 1 was employed, at an excitation frequency of 400 cps. Dimensions of the reactor cores are given in Fig. 3. The material is a General Ceramics Corporation ferrite, "Ferramic H." The annular winding was used for applying the divisor control signal and obtaining the output, while the excitation and the dividend control signal were applied to the toroidal winding. The pertinent parameters are

$B_S\approx 3{,}250$ gausses $=0.21(10^{-3})$ weber/inch^2
$H_C\approx 1$ ampere-turn/inch
$A_1l_1=A_2l_2=0.686$ inch^3
$A_1=0.570$ inch^2; $A_2=0.147$ inch^2
$l_1=1.204$ inches; $l_2=4.66$ inches
$N_1=200$ turns; $N_2=800$ turns
$a=1.034$
$R_1\approx R_2\approx 11$ ohms

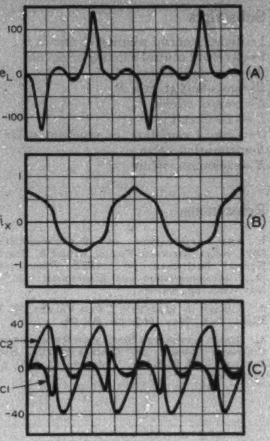

Fig. 15. Oscillograms illustrating operation outside of division mode, with no load

Voltage scales in volts
Current scale in amperes
$E_X=70$ volts
$2I_1=0.25$ amp
$2I_2=1.0$ amp

The impedances Z_1 and Z_2 were chokes of approximately 50 millihenrys.

Figs. 8, 9, and 10 show the results of varying one of the parameters E_X, I_2, and I_1 respectively, while the other two remain constant. The no-load output voltage E_{LO} and the output voltage E_L with resistive load R_L are the dependent variables. When R_L is 1 ohm, the load voltage E_L numerically approximates the load current with the load windings short circuited. With logarithmic scales, a straight line at an angle of +45 degrees shows direct proportionality and a straight line at an angle of −45 degrees shows inverse proportionality. It is observed from Figs. 8 and 9 that multiplication of E_X and I_2 is preserved with loading, while Fig. 10 indicates that division by I_1 is destroyed by excessive loading.

Comprehensive tests were made to determine the accuracy of equation 28. The data are interpreted in terms of an empirical factor k to be used in the equation

$$E_{LO}=kE_X\frac{I_2}{I_1} \tag{50}$$

Over a wide range of the independent variables E_X, I_1 and I_2, the factor k lies within the limits of 0.7–1.0, or a median value of 0.85 with an error of ±17.6%.

The region is mapped in Fig. 11, and the general boundaries may be described approximately as

$$b_2\leq 0.35 \tag{51}$$

$$a\frac{|I_2|}{|I_1|}\leq 0.8 \tag{52}$$

The boundaries defined by equation 51 and 52 are shown by dashed lines in Fig. 6, and verify the analytical predictions of inequalities 29 and 30.

Additional boundaries, attributed to the finite width of the hysteresis loop of the core material, are approximately

$$\frac{N_1I_1}{l_1}\geq 5H_C \tag{53}$$

$$\frac{N_2I_2}{l_2}\geq 0.5H_C \tag{54}$$

An upper limit to the value of I_1 is implied when the winding resistances are neglected, and may be expressed as

$$I_{XO}R_2<<\frac{E_X}{2} \tag{55}$$

which in view of equation 34 becomes

$$I_1R_2<<a\sqrt{2}\,E_{S2} \tag{56}$$

Actually, the reactors become thermally limited when $2I_1$ is approximately 2 amperes. There also appears to be a lower limit to the value of the excitation voltage, attributed to unbalance between the reactors and other stray effects. The excitation current I_{XO} is quite close to the value of equation 34, provided that

$$a\frac{|I_2|}{|I_1|}<0.2 \tag{57}$$

Greater accuracy is possible if the range of the variables is more restricted. For example, Fig. 12 defines the range of the d-c control signals within which the factor k is 0.85±6%, with a constant value of excitation.

Oscillograms which illustrate steady-state operation at a typical point in the division mode are presented in Fig. 13. The waveforms verify the equations derived in the analysis. A sequence, showing the effect upon the load voltage e_{LO} of doubling each of the quantities E_X, I_1, and I_2 in turn, is formed by Fig. 13(F) and Fig. 14(A), (B), and (C). The changes observed confirm the prediction of equation 28.

An example of the type of operation which occurs when the restrictions of equations 51 and 52 are grossly violated is shown in Fig. 15. The conclusions reached by inspection of Figs. 6 and 7, mentioned in the section on operation outside of the division mode, are confirmed.

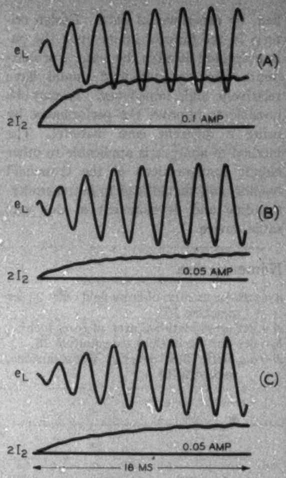

Fig. 16. Response of load voltage and dividend control current to a step input of dividend control voltage

$E_X=10$ volts
(A) $2I_1=0.64$ amp; $R_{C2}=7.5$ ohms; $\tau_2\cong$ 3.2 milliseconds
(B) $2I_1=0.32$ amp; $R_{C2}=15$ ohms; $\tau_2\cong$ 4.0 milliseconds
(C) $2I_1=0.32$ amp; $R_{C2}=7.5$ ohms; $\tau_2\cong$ 6.5 milliseconds

Three examples of the response to a step input applied to the dividend control circuit are presented in Fig. 16. The external choke Z_2 was removed from the circuit and replaced by resistance. The values of the time constant τ_2 calculated from equations 43 and 45 for the conditions of Fig. 16(A), (B), and (C) respectively are 5.35, 5.35, and 10.7 milliseconds, which are in fair agreement with the approximate measured values stated in the caption of Fig. 16.

Conclusions

A pair of cross-field reactors can be employed to perform the operation of analog division. The arrangement has the advantages of simplicity, ruggedness, ability to operate under severe environmental conditions and reasonable accuracy for a wide range of the divisor and dividend control signals. These attributes are important in many applications, such as automatic control systems.

An adequate analysis of the no-load condition has been presented and verified, by experimental data. Design criteria in the form of limits upon the parameters are listed in the text. For maximum accuracy, the load should have relatively high impedance. It may be possible to improve the performance by using a different core material. The method of analysis is applicable to other circuit configurations of the cross-field reactor, and should lead to better understanding and development of this versatile device.

Nomenclature

a = area-turns ratio of cross-field reactor; see equation 15
A = net cross-sectional area of core, inch^2
b_2 = per unit excitation, see equation 18

A Transposition System for Carrier Systems Up to 156 Kc

BESS M. KIRKLAND
MEMBER AIEE

THIS PAPER describes a new transposition system designed to fulfill needs in Alabama. The system permits the use of much longer spans than those required by previous transposition designs intended for operation of carrier systems in the range up to 156 kc, and thereby provides for excellent economies in preparing open-wire toll lines for such facilities.

The widespread demand from the public, industry, and the government for more and better communication service has caused an appreciable increase in the use of open-wire carrier systems despite extensive construction of cable and microwave radio relay systems. Dispersal of industry to small towns and the trend toward suburban living have brought a need for toll circuits to areas once considered dormant.

The application of compandored carrier systems has made this circuit growth feasible by open-wire lines. These systems are being manufactured in quantity by many companies, and the inclusion of compandors makes them economically attractive by permitting less stringent construction requirements than those for noncompandored multichannel systems.

Major economies in the use of compandored systems are effected in a transposition system developed by the Bell Laboratories. Known as the *O-1* design, this system is based on the use of 12-inch pin spacing and 4-inch point transposition brackets. The equivalent of 8-16-8 inch pin spacing is obtained by the installation of pinch brackets at specified locations. A 2-span transposition interval based on nominal pole spacing of 155 feet establishes the maximum lengths for the transposition sections. Some existing lines on which compandored systems could be used to excellent advantage have, however, an average span length which exceeds that of the *O-1* design.

The Montgomery-Smithville Toll Line, from Montgomery to Eufaula, Ala., is a line of this type. An expected increase from 41 circuits in 1957 to 85 circuits in 1965 required the installation of two *OB*, four *OC*, and three *OD* systems in 1958. The transposition system on this 2-arm route was not suitable for systems in the *OC* and *OD* range, and *OB* systems were in service on the four assignments suitable for their use. Seventy miles of the line had a nominal span in excess of 200 feet, while only 7 miles were spaced to conform with *0-1* requirements. Reconstruction of this line, which had a maximum of 20 toll wires, all 104 copper Standard Wire Gage no. 12, necessitated the replacement of 35% of the poles and two pairs of wires.

Three plans for solving the transposition problem were considered. The first consisted of reconstructing 70 miles of line to meet *0-1* spacing requirements by relocating approximately half of the poles to be replaced and increasing by 45% the number of poles and crossarms in the route. Adapting the *0-1* design to a 1-span interval was the second

plan considered, but the use of 8-inch brackets, to provide 8-16-8 inch pin spacing, with spans more than 200 feet in length would result in excessive wire slapping[1] for the type service required. The third plan was to design a new transposition system for this type of route. Because use of the *0-1* design under these circumstances was economically undesirable, and because its adaptation would have impaired transmission, the design of the new system was undertaken.

Such a system must provide crosstalk coupling loss of at least 30 decibels between pairs to insure satisfactory performance of like compandored carrier systems in the frequency range up to 156 kc. The transposition interval for crosstalk control in this frequency range necessitated a 1-span interval if the existing spacing were to be retained. This shortened the section lengths sufficiently to permit the use of 12-inch point-side brackets instead of the 4-inch transposition brackets and pinch brackets employed in the *0-1* design. The selection of suitable transposition types[2] to control systematic crosstalk at the frequencies involved was extremely critical with the near-end and far-end coefficients resulting from 12-inch pin spacing. Poling types for junction transposition designs were selected carefully to reduce type unbalance crosstalk between all pair combinations.[3] The pole spacing unbalance of three times the section length[1] (*3L*) was achieved largely by relocating deteriorated poles without increasing appreciably the number of poles in the line. Maximum wire sag difference for wires of a pair was established at 3 inches with an average of 1 inch. These limitations were specified to control adequately the components of random irregularity crosstalk.

Fig. 1 shows the fundamental types chosen for the longest section of the system, while Table I lists the types for two arms for all the sections. Computations and experience have shown the types chosen to be satisfactory for noncompandored systems using staggered frequencies, or compandored systems without staggering advantage, in the range up to 40 kc The hardware required for this design is approximately the same as that needed for the *0-1* for two arms, but consider-

ably less than the *0-1* for one arm, the types employing fewest brackets having been assigned to the first arm. Inasmuch as a line with more than eight carrier pairs would have shorter pole spacing, this design, known as the *B1*, was developed for only two arms. The fundamental premise of the system was that it would meet the crosstalk coupling loss requirements of compandored carrier systems in the range up to 156 kc.

Extensive crosstalk computations, combined on a repeater-section basis, were made prior to the installation of the system, and indicated satisfactory performance. After the retransposing was completed, more than 11,000 tests were made on the circuits. These tests included near-end and far-end readings made at the ends of a repeater section with each circuit disturbed and all other circuits taken as the disturbing circuit, one at a time. The frequency range covered in the tests was 40 to 150 kc, with the readings taken at intervals of 2 kc. With test points established at the *S* points of the longest of the long-type sections, the same procedure was followed on a sectionalized basis. Fig. 2(A) through (D) indicates the worst conditions for far-end crosstalk tests made on a repeater-section basis. This is a resultant far-end coupling including reflected near-end crosstalk and interaction effects. The lowest measurement was 34 decibels. Fig. 3 shows an attenuation curve for a typical pair. No undesirable absorption peaks were encountered.

Conclusions

The *B1* design will furnish eight assignments for compandored carrier systems in the frequency range up to 156 kc, or a total of 130 circuits if the pole pairs are used. A maximum average span of 220 feet can be utilized with 12-inch pin spacing and 12-inch point-side brackets. Pole-spacing deviation of three times the section length is permissible, with a maximum wire sag difference of 3 inches, and an average of 1 inch, between wires of a pair. Junction transpositions should be carefully installed in accordance with the poling scheme, shown in Table II, for the long sections, with wires being returned to zero polarity upon entering the shorter sections. The *B1* requires a minimum of ten poles per mile fewer, or 29% less, than the *0-1* design. This savings in poles represents a marked economy in building and maintaining open-wire routes. For systems composed of several repeater sections, improved performance can be obtained by assigning two like systems occupying circuits which have a low crosstalk coupling loss in one repeater section to pairs having a high crosstalk coupling loss in the next repeater section.[1] Further improvement is possible by omitting the pole pairs. The *B1* transposition system met the requirements for the Montgomery-Smithville Toll Line, and it can be utilized to advantage on many similar lines, including routes of the Bell System, independent telephone companies, and railroad routes.

A Rod-Position Indication System for Pressurized Reactors

R. C. FLOYD
MEMBER AIEE

J. F. REUTHER
MEMBER AIEE

THE MOST practical present-day systems for determining the absolute position of reactor control rods without penetrating the pressurized enclosure are those which detect the position of magnetic material in the rod extension. It is the purpose of this discussion to describe such a system and to outline the solutions to some of the detail design problems encountered in its development.

A simplified schematic diagram of the system is shown in Fig. 1. The detector is a long slender coil, the inductance of which is varied as the hollow magnetic rod extension passes over it. The change of inductance is a measure of rod position and is used to light a limit light and operate a position indicator. The detector is in one leg of an Owen bridge. The output of the bridge is rectified by a transistorized phase-sensitive demodulator and fed into the control winding of a magnetic amplifier (preamplifier). This preamplifier is driven from cutoff to saturation in a relatively small portion of the rod travel and its output is fed into the next stage of magnetic amplification (lamp amplifier). The lamp amplifier turns on a lamp that indicates to the operator that the rod is close to its bottom position. The position at which the lamp comes on is adjustable by controlling the bias on the preamplifier using potentiometer *P*1. Bistable magnetic amplifiers were not used since experimentally they were very sluggish with the large power gain required. A selector switch (*S*1) is used to switch a milliameter to read the line voltage by connecting it to the bias supply through suitable resistors or to read the position of any detector by connecting it to the output of the phase-sensitive demodulator. All magnetic amplifiers and lamps are de-energized when reading a rod position since the lamps are out of calibration at this time. A continuously adjustable autotransformer is used to adjust the supply voltage before reading.

Design Considerations

The main design objective was to obtain an output from the unbalanced bridge which varied linearly with rod position. The major design problems resulted from unwanted variables dependent on voltage, temperature, or frequency. Specified

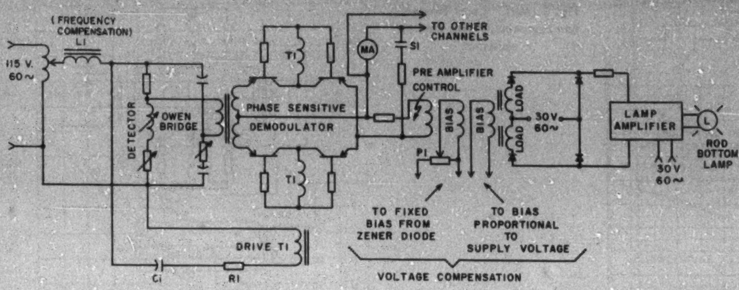

Fig. 1. Simplified schematic of rod position indication system

operating conditions included: line voltage regulation of ±10%, frequency $\pm 4^1/_4\%$, ambient temperature of detector from 40 F (degrees Fahrenheit) to 350 F, and ambient temperature of receiver from 40 F to 149 F. In addition to selecting accurate and stable components, it was necessary to compensate for the following variables:

1. Detector coil resistance with temperature.
2. Detector coil inductance with temperature.
3. Detector coil inductance with voltage.
4. Bridge output with frequency.
5. Meter resistance with temperature.
6. Capacitors with temperature.

Balanced Owen Bridge

Before considering the various compensations in detail, it is well to review the characteristics of the Owen bridge since all measuring system components are essentially part of the bridge.

The Owen bridge is shown in Fig. 2. L_u is the general unknown inductance while L_{uo} refers to the unknown inductance under balance conditions. The balance equations are available in handbooks and are

$$L_{uo}=ASC_B \tag{1}$$

$$U=(C_B/C_A)S \tag{2}$$

No literature was available on the operation of the bridge under unbalanced conditions. A mathematical investigation showed C_A should equal C_B for maximum bridge output voltage. Also, it is desirable to have the bridge internal impedance close to minimum. For a particular application, a minimum impedance of 130 ohms was obtainable for $C_A/C_B=3$ but using $C_A/C_B=1$ only increased the impedance to 150 ohms. It was therefore decided to let $C_A=C_B$.

The value used for C_A and C_B was called C while the value used for U and S was called R. Then, the bridge internal (looking in) impedance at balance is

$$Z_{34}=(R+1/jwC)(1+jwL_{uo}/R)/(2+jwL_{uo}/R) \tag{3}$$

Also the bridge impedance (load seen by the source voltage E_{in}) at balance is

$$Z_{12}=(2R+jwL_{uo})/(1+jwRC) \tag{4}$$

Unbalanced Owen Bridge

INDUCTANCE UNBALANCE

If the detector inductance increases from L_{uo}(value at balance) to L_u, then the open circuit output voltage is:

$$E_{out}=E_{in}(jw)(L_u-L_{uo})/[4R-\omega^2L_uL_{uo}/R+2jw(L_u+L_{uo})]$$

For a particular case the magnitude of E_{out} can be approximated within 1% over the range as:

$$|E_{out}| \approx \text{(approximate equals)}\ |E_{in}|\omega(L_u-L_{uo})/(4R)(1.025) \tag{5}$$

Note that the output varies with the change of inductance.

FREQUENCY DEPENDENCE

While the bridge is theoretically insensitive to frequency at balance, its output under unbalanced conditions is approximately directly proportional to frequency (see equation 5).

RESISTANCE UNBALANCE

If the bridge is balanced and then resistor U is changed (detector coil resistance varies with temperature), the output will be as follows:

$$E_{out}=E_{in}(U/R-1)/(2+2U/R-\omega^2L_{uo}^2/R^2+(3+U/R)jwL_{uo}/R) \tag{6}$$

The denominator stays reasonably constant. The output voltage then varies directly with the error in U. In a particular application, a change of 0.5% in U gave an output equivalent to 3.7% of full rod travel.

CAPACITANCE UNBALANCE

If the bridge is balanced and both capacitors are changed slightly (due to ambient temperature change) the bridge will have an output, as shown by the following:

$$E_{out}=E_{in}jwL_{uo}(1-C/C_o)/R[4-(C/C_o)(\omega^2L_{uo}^2/R^2)+2jwL_{uo}/R(1+C/C_o)] \tag{7}$$

C_o is the value of C at balance. The denominator does not vary much with C, so, approximately:

$$|E_{out}|=|E_{in}|4R(1-C/C_o)/\omega L_{uo} \tag{8}$$

Quantitatively for a specific case, a change in C of 1.7% results in an output of 3.7% of full rod travel.

Compensation

Returning now to specific compensation methods, it is natural to start with the resistance variation of the copper

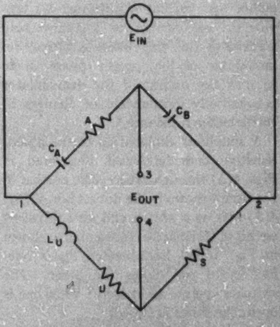

Fig. 2. Owen bridge

F—Output diagram

detector winding over the wide range of operating temperature (4 C (degrees centigrade) to 177 C), resulting in a change of about 68%. This was corrected to approximately ±6% by local compensation with Nichrome* wire and thermistors, and to less than ±0.25% by phase-sensitive circuitry at the receiver. The method of local compensation is illustrated in Fig. 3, which shows resultant leveling achieved by summing three characteristic curves of resistance versus temperature.

The remote compensation for detector resistance change with temperature is based on the fact that the output voltage of the Owen bridge due to resistance unbalance is approximately 90 degrees out of phase with the output of the bridge due to inductance unbalance. Referring to Fig. 1, condenser *C*1 and resistor *R*1 together with current transformer *T*1 provide driving current to the switching transistors in the phase-sensitive demodulator of the proper phase angle so that the output of the demodulator is essentially independent of changes in the detector resistance.[1]

A simplified explanation of the phase-sensitive demodulator is illustrated in Figs. 4(A) through 4(F). The portion of the circuit shown in the dotted box of Fig. 4(A) acts as a switch and an equivalent circuit of this may be represented as shown in Fig. 4(B). Each switch opens one-half cycle and closes the other. The switches operate alternately; when one is open, the other is closed.

Assume that the top switch closes as soon as the a-c input changes polarity so that the terminal with the polarity *X* is positive. The d-c output has the polarity shown. When the a-c input reverses polarity, assume that the top switch opens and the bottom switch closes. The d-c output again has the same polarity and this amounts to a synchronous rectifier. The output is shown in Fig. 4(C).

Now assume that switches act at some time later than current zero and actually do their switching at an angle θ. Since the switch can carry current in both directions, the output will then appear as shown in Fig. 4(D). An extreme condition would be $\theta = 90$ degrees, in which case the output would look like Fig. 4(E). Note that the net d-c is zero. If θ is greater than 90 degrees but less than 270 degrees, the output reverses polarity.

The average (d-c) value of the output if the input is $E_m \sin wt$ is

$$E_{dc} = (1/\pi)\int_{\theta}^{\pi+\theta} E_m \sin (wt) d(wt) \tag{9}$$

$$= -(E_m/\pi) \cos (wt)\Big|_{\theta}^{\pi+\theta} = (2E_m/\pi) \cos \theta$$

$$= E_{rms} \text{ a-c input } (\cos \theta)/1.11 \tag{10}$$

The d-c output is proportional to the phase angle between the a-c input and switching action. If $\theta = 90$ degrees, the output is zero since cos 90 degrees = 0.

The switching transistor circuit acts similarly. During one half-cycle, one pair of transistors are driven to saturation and act as a closed switch while the other pair are cut off and act as an open switch. During the next half-cycle their action is reversed.

The angle θ used to describe the action of the synchronous switches is now the angle between the a-c input voltage and the a-c driving current. The same cosine law applies.

The output of the Owen bridge under unbalanced conditions consists approximately of two components. One is due to unbalance of inductance while the other is due to the unbalance of the resistance in the inductive leg. These two components are approximately 90 degrees out of phase. The first component is used for metering while the second introduces undesired errors.

If the transistor driving voltage is in phase with the desired component, the effect of the undesired component will be minimized. Referring to Fig. 1, resistor *R*1 and condenser *C*1 are chosen to give the desired transistor driving current at the desired phase angle. The resistors in series with the transistor bases help divide the driving current equally between transistors.

Using the phase angle of the desired component as a reference, the bridge output may be shown as in Fig. 4(F). The desired component is $E \cos \theta$. The output of the bridge E is the a-c input to the phase-sensitive demodulator. The phase-sensitive demodulator output is ($E \cos \theta/1.11$) where E is in rms volts and the output is in d-c volts.

It is apparent from this that, in addition to the fact that the phase-sensitive

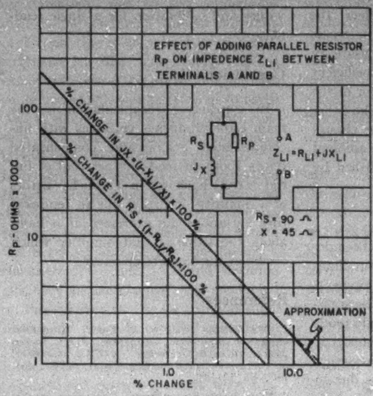

Fig. 5 (left). Shunting resistor effect

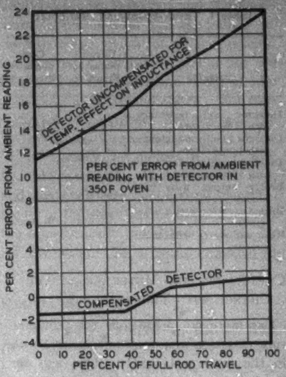

Fig. 6 (right). Compensation for inductance change with temperature

demodulator makes it practical to rectify the low-voltage output of the Owen bridge, it also minimizes the errors attributable to changes of resistance in the detector inductance winding caused by changes in temperature.

Variations of Detector Inductance with Temperature

Temperature tests indicated that the inductance of the detector varied with temperature, approximately 4% increase at each rod position linearly from 90 F to 350 F. Compensation for this variable was approached on the basis that: 1. addition of a resistor (R_p) across the detector-coil terminals will decrease the reactance seen by the bridge, and 2. a thermistor-resistor combination used for the parallel resistor could possibly vary with temperature in such a way as to automatically change the effective reactance to compensate for the change of detector-coil inductance with temperature. Where R_s is the detector resistance, the compensating circuit was developed as follows:

$$Z_{L1} = R_p(R_s + jX)/(R_p + R_s + jX) \quad (11)$$

$$Z_{L1} = (R_p^2 R_s + R_p R_s^2 + R_p X^2)/(X^2 + (R_p + R_s)^2) + jXR_p^2/(X^2 + (R_p + R_s)^2) \quad (12)$$

where X is the detector reactance and Z_{L1} is the impedance of the compensated detector, as shown in Fig. 5.

The real term of equation 12 shows that the equivalent series resistance has changed; however, the phase-sensitive demodulator is insensitive to small changes of resistance. The imaginary term shows that adding R_p reduces the effective reactance by $R_p^2/(X^2 + (R_p + R_s)^2)$. The correction in X is $1 - R_p^2/(X^2 + (R_p + R_s)^2)$. For corrections of about 5%, X is negligible in the denominator (in the range of R and X encountered) and the correction becomes:

$$1 - R_p^2/(R_p + R_s)^2 = 1 - 1/(1 + R_s/R_p)^2 = 2R_s/R_p - 3(R_s/R_p)^2 + 4(R_s/R_p)^3 \ldots \quad (13)$$

Only the first or first two terms of equation 13 are significant. The correction factor versus R_p plotted on log-log paper is a straight line according to Fig. 5. Even the first term $2R_s/R_p$ is only off 0.15% at 4% correction so that a good approximation for the correction is $2R_s/R_p$. The change in effective series resistance was also calculated to ensure that it would not be excessive. From these calculations it was indicated that the correction factor for resistance is approximately $3R_s/4R_p$ compared with $2R_s/R_p$ for reactance. This correction factor for resistance is also plotted in Fig. 5, and the relationship between the two factors is approximately:

$$(\%\text{ change of } R) \approx 3/8\ (\%\text{ change of } X) \quad (14)$$

The characteristics of the thermistor required were taken from data thus calculated and a set of curves showing effect of the compensation for inductance variation with temperature on a production channel is shown in Fig. 6.

Variation of Inductance with Bridge Supply Voltage

Tests showed that if the Owen bridge was balanced at one voltage it would not be balanced at another input voltage level. This was apparently due to variation of the detector inductance with ampere turns, and compensation was desirable. No problem would result when metering since adjustment of voltage with the control provided was a procedural requirement when reading rod position on the test channels. However, the rod bottom-indicator circuitry must be operative under all voltage conditions; hence, compensation for voltage variations was accomplished by providing two biases for the amplifiers, one fixed from a Zener diode and one that varies with supply voltage.

Frequency Compensation

Frequency compensation is necessary since the unbalanced Owen bridge is sensitive to frequency (see equation 3). The output voltage is proportional to both ω and the input voltage. If the product is held constant the bridge would be frequency insensitive. This was approximated by adding a choke in series with the bridge and using a higher supply voltage. Calculation showed that about 1.3 henrys would be optimum in this case, as indicated by the plot shown in Fig. 7.

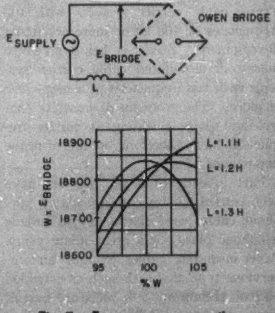

Fig. 7. Frequency compensation

Table I. Error-Producing Variables

Variable	Uncompensated Error, %	Compensated Error, %
Detector coil resistance with temperature	±250	±0.25
Detector coil inductance with temperature	± 5	±1.5
Detector coil inductance with voltage	± 6	±0.9
Bridge output with frequency	± 5	±0.35
Bridge capacitors with temperature	± 2.7	±0.25
Read-out meter with temperature	± 1.5	±0.15

CAPACITANCE AND METER RESISTANCE CHANGE WITH TEMPERATURES

Two more compensations for temperature variation were found necessary, both in the receiver circuitry. One was for the bridge capacitors, which were found on test to vary with temperature more than anticipated. The solution to this unwanted variable was to select the capacitors with a negative characteristic within certain limits and compensate by using a positive temperature coefficient resistor in series with the resistor in the capacitive leg of the bridge. The other compensation was for resistance change in the meter over the rather wide ambient specified, and this was accomplished by the thermistor method.

GENERAL

The error compensations have been described on the basis of independent channels of rod position indication equipment. It may be noted from Fig. 1 that the application discussed employed a single read-out instrument with means to transfer it to multiple channels. Overall accuracy of the system was somewhat less due to the necessity of matching channels with resultant compromise of compensating values and calibration for a single read-out.

Conclusions

In conclusion, recapitulation of the main error-producing variables with uncompensated errors and compensated errors (both in read-out per cent of full rod travel) is shown in Table I. Errors in a quantity occurring due to temperature variations are expressed as a band about the value of that quantity which occurs at the mean temperature.

IN THE LAST few years, amplitude-modulated carrier telephone systems up to about 250 kc have been routed over polyethylene toll cables and frequency-modulated carrier telephone systems up to about 350 kc have been routed over entrance cable for open-wire circuits. Trunk cable carrier systems with top frequencies of 400 kc or more are under development. Study is being given to pulse-code-modulated cable carrier systems with top frequencies of a megacycle or more. The problems of crosstalk control and noise shielding at carrier frequencies have, therefore, become of prime importance.

Past investigations of this sort have been carried out for paper-insulated telephone cables used extensively in outside telephone plant for a great many years. Paper-insulated cables require an impervious type of sheath such as extruded lead or aluminum or a moisture barrier such as Stalpeth.[1]

In the past decade plastics have become of interest for telephone cables with development centered around polyethylene because of its low dielectric constant, low power factor, high dielectric strength, and electrical stability over a wide frequency range.

In present-day constructions, polyethylene-insulated telephone cables are used in 19, 22, 24, and 26 Awg (American wire gage) copper conductors, and cable sizes up to 900 pairs. They are engineered to have the same mutual capacitance as the standard types of paper cables in order to allow interchangeability and the use of standard loading systems. Cables intended for exchange area use are nonquadded and are designed for average mutual capacitance of 0.083 μf (microfarad) per mile and toll grade nonquadded cables are designed for average mutual capacitance of 0.066 μf per mile.

Until quite recently, polyethylene-insulated telephone cables have been used mostly for the transmission of voice frequency. A cable design to control crosstalk between circuits properly has offered little difficulty. Also, the problem of shielding the cable pairs from external fields at carrier frequencies has seldom been encountered.

Comparatively little transmission data have been published on the types of thermoplastic telephone cable in current use. Attenuation data[2] up to 300 kc are available on older types of cables. It is the purpose of this paper to present a study of the transmission and crosstalk properties of standard, paired, polyethylene-insulated, fully color coded, and Alpeth-sheathed cables throughout the audio- and carrier-frequency range up to 1,000 kc including the effects of temperature variation and moisture on cable parameters. A study of shielding in the same frequency range is also made.

Cables Tested

Most measurements on parameters and all measurements on crosstalk were made

---

Paper 59-778, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 23, 1959; made available for printing April 9, 1959.

G. S. EAGER, JR., L. JACHIMOWICZ, I. KOLODNY, and D. E. ROBINSON are with the General Cable Corporation, Bayonne, N. J.

The authors acknowledge the help and advice of A. G. Chapman, Consulting Engineer, throughout this program and the assistance of J. A. Olszewski, General Cable Corporation, in making measurements and evaluation of the data.

Vol. 7
Pt. 1
1959

on a 100-pair cable, 19 Awg copper conductors, the core being made of four units each consisting of 25 pairs having different twist lengths. The average mutual capacitance was 0.083 μf per mile and this cable henceforth will be referred to as 19 Awg 0.083 cable. The Alpeth sheath consists of a folded, corrugated aluminum tape 8 mils thick with an over-all black, high-molecular-weight polyethylene jacket. Surrounding the cable core and directly under the corrugated aluminum tape is a bedding consisting of a laminate GR-S rubber and Mylar tape having a thickness of 16 mils. Certain shielding efficiency measurements were conducted on this cable as well as on a similar cable having 2 helically applied aluminum tapes each 5 mils thick in lieu of the 8-mil folded corrugated tape.

Additional parameter tests were conducted on two similar 100-pair cables, one in size 19 Awg having an average mutual capacitance of 0.066 μf per mile and made up of six units each consisting of 16 or 17 pairs; the other in size 22 Awg having an average mutual capacitance of 0.083 μf per mile and made up of four units each consisting of 25 pairs. These will henceforth be referred to as 19 Awg 0.066 cable and 22 Awg 0.083 cable, respectively.

All of these cables were chosen as typical of normal production and were placed on wooden reels to eliminate the presence of steel in the vicinity during measurements.

Test Conditions

Most measurements of parameters were made on a reel of cable 180 feet long. Certain measurements were made on other lengths of the same cable because of measuring difficulties encountered on this length; to measure the conductance, a 20-foot length for the highest frequencies and a 3,000-foot length the lowest frequencies were employed. For most measurements it is convenient to choose a sample about 10 feet in length. However, this has the undesirable features that such a sample is insufficient in length to give representative results and that the end effects introduce errors which may make the measurements questionable. Consequently, it is necessary to choose a longer sample. However, caution must be exercised in the choice of test length with regard to wavelength in order to avoid having the open-circuit admittance appear as a short-circuit impedance and vice versa. Although such a condition can be tolerated and correct parameters determined by the methods described later, it is quite inconvenient. For these reasons a 180-foot length of cable was chosen for the bulk of the measurements. Such a length was found convenient for all frequencies studied and had the additional advantage that such a reel length could be conveniently placed in the tempeature-controlled rooms utilized in this study. The temperature range studied was from 0 F (degrees Fahrenheit) to 140 F and was maintained constant by automatic temperature controls. It is quite difficult to maintain the cable temperature precisely stable throughout its length, and for this reason the d-c resistance of the cable pair under test was periodically measured with a d-c Kelvin bridge and these measurements used to establish the average cable temperature at any time during the testing period.

Crosstalk measurements were made on a reel of cable 3,000 feet in length in order to obtain more accurate data on a long length of cable although a length shorter than 1/4 wavelength would have facilitated measurements since reflections at terminations of circuits would be only minor in nature. Each of the four units of the test length was paired and stranded in a 6,000-foot length, which is customary manufacturing procedure. Two cables were then obtained. Each was 3,000 feet in length and was composed of four units, each produced in separate runs. The test cable was kept in a shielded, insulated chamber at a controlled temperature of 68–70 F. For tests, all cable pairs were terminated in suitable networks with midpoints grounded.

Shielding studies were made at room temperature (75–85 F) on a cable length of approximately 10 feet.

Primary and Secondary Parameters

Rather than make measurements on all pairs in the cable at all temperatures and frequencies a preliminary study was made at 80 F of all pairs within the cable to establish the variation of parameters between pairs and to enable the choice of several representative pairs upon which to make the bulk of the measurements. The maximum variation at 1 kc from average values for all 100 pairs of the 19 Awg 0.083 cable for the a-c resistance was ± 1%; for mutual capacitance, ±4% in two units and ± 3% in the other two units; and for inductance, ±2%. The variation at 1 kc in conductance was not determined on the 180-foot reel because the values were less than the reliable range of the bridge. On a 3,000-foot reel of similar cable the conductance of all pairs was found to vary between 0.5 and 2.0 μmho (miromho) per mile at 1 kc. The variation between pairs of unit 3 at various frequencies was measured and the maximum variation from average values for resistance was ±1% for all frequencies; for mutual capacitance, ±4% for all frequencies; for inductance, ±2% at 1 kc and ±3% at 20 kc and above. For conductance at higher frequencies the variation was large, as it was at 1 kc.

The primary parameters (R, L, C, and G) and the secondary parameters (Z, α, β, and velocity) were obtained by measurements of the short-circuit impedance and the open-circuit admittance and by using equations 24 to 28 as indicated in Appendix II.

Resistance

The results obtained on the 19 Awg 0.083 and the 22 Awg 0.083 cables are given in Fig. 1, where the change of resistance with frequency and with temperature is shown. The resistance of the 19 Awg 0.066 cable is not plotted but the resistance of this latter cable was measured at 80 F and found to be equal to the 19 Awg 0.083 cable at low frequencies and, as would be anticipated, slightly less at the higher frequencies. The measured resistance and that computed from cable dimensions for the 19 Awg 0.066 cable at 1,000 kc were 432 and 396 ohms per mile, respectively. The change with frequency is minor up to 20 kc. In the frequency range of 20 kc to 300 kc the change is quite rapid and above 300 kc the change is very rapid. The effect of temperature on the resistance becomes less on a percentage basis as the frequency increases, as may be seen from Fig. 2 also.

The resistance increases as the frequency increases because of (1) skin effect in the individual conductors; (2) proximity effect in one conductor because of the presence of the other conductor in a

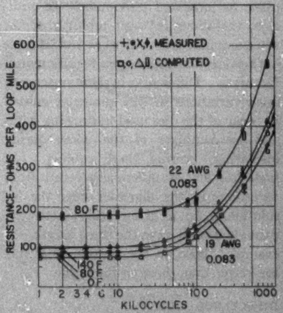

Fig. 1. Resistance per loop mile versus frequency

given pair; and (3) eddy current losses in the surrounding pairs and sheath. The a-c resistance may be computed from cable dimensions with good accuracy from the following:

$$R_{ac}=R_{dc}+\Delta R_s+\Delta R_p+\Delta R_1 \qquad (1)$$

where

R_{dc} = d-c resistance
ΔR_s = increment due to skin effect
ΔR_p = increment due to proximity effect
ΔR_1 = increment due to eddy currents in other pairs and the sheath

The component ΔR_1 is small at low frequencies and may be neglected for most practicable purposes for frequencies up to 50 kc; Appendix III gives the method by which equation 1 may be employed to estimate the a-c resistance of a pair for a cable having a folded corrugated aluminum sheath or equivalent. The estimated a-c resistances as computed from cable dimensions using equation 1 are shown in Fig. 1.

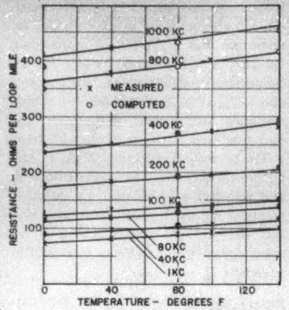

Fig. 2. Resistance per loop mile versus temperature for 19 Awg 0.083 cable

It is reasonable to expect variations in the parameters between pairs in a given cable as indicated previously. In addition, variations between cables from the same manufacturer will occur and likewise between similar cables from various manufacturers. Differences in resistance result from variations in wire diameter caused by wear of the dies used in drawing wires and by handling of the wires during insulating, pairing, and cabling. (At high frequencies differences result from variations in the diameter over the insulation.) In a given reel length the pairs do not all have the same length, for example, those on the outside of a unit are longer than those on the inside.

INDUCTANCE

The results obtained on the 19 Awg 0.083, 19 Awg 0.066, and 22 Awg 0.083 cables are given in Fig. 3 where the change of inductances with frequency is shown. Actually, the inductance changes little with frequency as compared to the changes observed in the resistance, and even less with temperature. The change with frequency is minor up to about 40 kc. In the range from 40 kc up to 1,000 kc the change is more important although at the higher frequencies the inductance is changing less rapidly because, at some frequency beyond 1,000 kc, the inductance will approach a constant value and not change with either frequency or temperature.

The inductance of the pair is reduced as the frequency increases because of skin effect in the individual wires. In addition to this, the proximity effect between the two wires of a given pair further reduces the inductance as the frequency increases. The inductance is further reduced by eddy currents flowing in adjacent pairs and in the sheath; however, both latter effects are small and only significant at frequencies above 750 kc.

The inductance of a pair of wires may be calculated[3] from the following formula:

$$L=[1.485\log_{10}2\,s/d+0.161l(x)]\times10^{-3} \qquad (2)$$

henrys per loop mile of the wire, where s is the center to center spacing of the wires of a given pair, d is the diameter of each wire, both in inches, and $l(x)$ is obtained from Fig. 24 for the applicable value of x given in equation 29. Equation 2 includes skin effect of the individual wires only. Slightly more accuracy may be obtained at higher frequencies ($x>2$) by using equation 2(A) which includes the proximity effect of the other wire of the pair.

$$L=\left[1.485\log_{10}\frac{d}{s-\sqrt{s^2-d^2}}+0.161Kl(x)\right]\times10^{-3} \qquad (2A)$$

where K is a correction factor of inductance for proximity effect and may be estimated as explained in Appendix IV. Equation 2(A) is a modified form of equation 2 and has been found to agree fairly well with the measured inductance. This equation does not include the effects of eddy currents in the surrounding wires and sheath; they reduce the inductance slightly at high frequencies. The value of inductance as given in equations 2 and 2(A) may be increased up to 2% to account for the additional length due to cabling and pairing.

The values of inductance computed from cable dimensions are given at 80 F for the three cables measured. The change of measured inductance with temperature is very small and the computed values are not shown for 0 F and 140 F although these may be estimated by using the proper values of x. Actually the only reason the inductance changes with temperature is because of an indirect effect from the change in resistance. As the resistance changes, the value of x changes and, consequently, the effects of skin and proximity effects change.

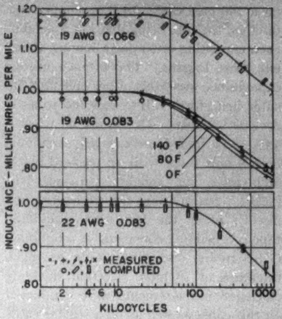

Fig. 3. Inductance per mile versus frequency

It is reasonable to expect variations in inductance due to manufacturing variations similar to those influencing the resistance. Variations in wire diameters, diameters in insulated conductors, and variations due to pairing and cabling are most important.

MUTUAL CAPACITANCE

The mutual capacitance did not vary to any significant degree over the complete temperature and frequency range studied. The maximum values on the pair tested were 0.082, 0.066, and 0.082 μf per mile for the 19 Awg 0.083, 19 Awg 0.066, and 22 Awg 0.083 cables, respectively; the corresponding minimum values were 0.081, 0.065, and 0.081. Such variations with frequency in mutual capacitance are believed to be due principally to experimental error and to a slight effect of the *GR-S* rubber-Mylar core tape. The dielectric constant of this core tape, which is placed in the cable for mechanical purposes, decreases somewhat as the frequency is increased and, since it is to a small extent in the electric field of the pair under measurement, the mutual capacitance decreases slightly as the frequency is increased.

The deviation of mutual capacitance of individual pairs from the average is due principally to their relative location with respect to the sheath, the tightness of the cabling, and variations in length of pair lays and cabling. Although these cables are fully color coded, the colors are chosen so as to not appreciably vary the dielectric constant of the polyethylene and, consequently, the mutual capacitance is not affected by this factor. The dielectric constant of polyethylene does not change significantly with temperature and with frequency over the range studied and, therefore, one would not expect the mutual capacitance to change.

The mutual capacitance of two wires in a medium may be expressed by the following well-known formula:

$$C=\frac{0.019415\times 10^{-6}\epsilon}{\log_{10} 2\, s/d}\ \text{f per mile} \tag{3}$$

where

ϵ = dielectric constant of the medium
s = center to center conductor spacing
d = wire diameter in inches

However, if the wires are surrounded by a dielectric which is the combination of polyethylene and air, this formula is not accurate unless modifications are made as indicated by Maupin[4] to calculate the effective dielectric constant of the medium surrounding the two wires. Moreover, in a cable, other wires are very near and the sheath is in the vicinity and effectively grounded, all of which results in a considerable modification of the mutual capacitance.

The following simplified formula, however, has been found useful for estimating the mutual capacitance of polyethylene insulated cables. The accuracy is generally within ±5%, which is only a little higher than the variation of capacitance between pairs found in the cable under study.

$$C=\frac{0.035}{\log_{10} 1.5\, s/d}\ \mu\text{f per mile} \tag{3A}$$

where s and d are the same as in equation 3. This formula gives a mutual capacitance of 0.085 μf per mile for the 19 Awg 0.083 cable, 0.066 for the 19 Awg 0.066 cable, and 0.082 for the 22 Awg 0.083 cable studied.

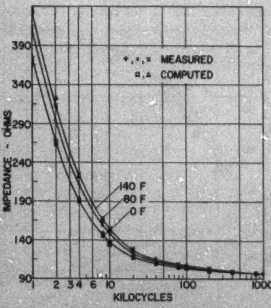

Fig. 4. Characteristic impedance, magnitude versus frequency for 19 Awg 0.083 cable

CONDUCTANCE

In polyethylene-insulated telephone cables, the conductance (also called mutual conductance) is extremely small and, in fact, may be neglected entirely when calculating the secondary parameters for all except frequencies in excess of 750 kc. For a normal cable, therefore, G is so small that it has no effect on the secondary parameters: impedance, velocity, phase shift, and attenuation. It was found difficult to obtain consistently reliable values of G when using equation 21 of Appendix II. Consequently, at the sacrifice of some accuracy, the conductance was measured on suitable lengths so that the open-circuit impedance yielded the conductance directly. Since the variation of conductance between pairs was large, care was taken to measure sufficient pairs to assure the tested pair was near the average. (The results obtained on the 19 Awg 0.083 cable are given in Fig. 10, where the change of conductance with frequency is shown along with values computed from cable dimensions using equation 4(A).) The change with temperature is very minor and has been neglected. The measured conductance of the 19 Awg 0.066 cable varied from about 1 μmho per mile at 1 kc to 290 μmho per mile at 1,000 kc and that of the 22 Awg 0.083 cable varied from about 1 μmho per mile at 1 kc to 330 μmho per mile at 1,000 kc. These values are valid throughout the temperature range of 0 F to 140 F.

The conductance of two wires in a medium may be expressed in accordance with the following formula:

$$G=6283\, fC\,(pf)\ \mu\text{mho per mile} \tag{4}$$

where

pf = power factor of medium
C = capacitance, μf per mile
f = frequency, kc

If the medium is a combination of polyethylene and air and other insulating materials, such as *GR-S* rubber-Mylar tape, are present, and if some contamination is present, it is impossible to derive an exact formula for calculating conductance. The power factor (pf) of colored polyethylene used in this cable varies from 0.0002 to 0.0005, depending on color. Experience has indicated, however, that the effective pf between wires in polyethylene-insulated paired cables is higher because of the afore-mentioned tape and contaminating particles. Consequently, if the capacitance (C) of equation 4 is replaced with that of equation 3(A) the following formula is very useful in estimating G.

$$G=\frac{0.154f}{\log_{10} 1.5\, s/d}\ \mu\text{mho per mile} \tag{4A}$$

where f is the frequency in kc, and s and d are the same as in equation 3. In this formula it is assumed that the conductance is not affected by temperature over the range of 0 F to 140 F. However, the variation of conductance between pairs is large as indicated previously and this equation must be used with this in mind.

IMPEDANCE

The characteristic impedance may be expressed as

$$\sqrt{\frac{R+j\omega L}{G+j\omega C}}$$

as given in equation 19 of Appendix II. For polyethylene-insulated telephone cable, G is negligible compared to $j\omega C$. At low frequencies, $j\omega L$ is negligible compared with R and the impedance is $\sqrt{R/j\omega C}$. At high frequencies, R is negligible compared with $j\omega L$ and the impedance is $\sqrt{L/C}$.

The magnitude of the impedance obtained on the 19 Awg 0.083 cable is given in Fig. 4 along with the values computed from cable dimensions at 0 F and 140 F obtained by utilizing primary parameters computed from cable dimensions and equation 19. The real and imaginary measured components are given in Fig. 5. The results obtained on the 19 Awg 0.066 and the 22 Awg 0.083 cables are given in Table I. The impedance decreases rapidly as the frequency is increased until

about 100 kc after which the decrease is minor. The impedance decreases rapidly because the component $j\omega C$ increases directly with frequency whereas the resistance changes very little, and, at low frequencies $j\omega L$ is small compared with the resistance. At the higher frequencies, the resistance is small compared with $j\omega L$, hence the decrease in impedance is due only to the slight decrease in the inductance. Since L, C, and G are affected little by temperature and R is appreciably affected by temperature, the impedance varies considerably from 0 F to 140 F at the low frequencies, whereas above approximately 20 kc the temperature has very little effect on the impedance; indeed, above 100 kc this effect may be considered negligible.

ATTENUATION

The results obtained on the 19 Awg 0.083 and 22 Awg 0.083 cables are given in Fig. 6, where the change of attenuation with frequency is shown. The results obtained on the 19 Awg 0.066 cable are given in Table I. The change of resistance of the conductors with frequency is the major contributor to the change of attenuation. The conductance of normal polyethylene-insulated cables is so low that it does not contribute to attenutation to any significant degree except at frequencies above 750 kc. The effect of temperature on attenuation is equally noticeable throughout the frequency range. Although the resistance is affected more by temperature at the lower frequencies than at the higher ones, the attenuation varies as the square root of the resistance at low frequencies but the loss contributed by series resistance varies directly with resistance at high frequencies. This results in the temperature having a more uniform effect on attenuation.

Once the primary parameters R, L, C, and G have been computed from cable dimensions, the attenuation may be computed by using equation 22 of Appendix II. In Fig. 6 and Table I, the values of attenuation computed from cable dimensions given are from equation 22.

PHASE CHANGE: VELOCITY

The results obtained on the 19 Awg 0.083 cable are given in Fig. 7 and on the 19 Awg 0.066 and 22 Awg 0.083 cables in Table I. The phase change increases rapidly with frequency; it is affected slightly by temperature.

By utilizing equation 23 of Appendix II the phase change may be computed from cable dimensions from the primary parameters previously computed. These computed values are shown for 80 F in Fig. 7 and Table I.

The velocity of propagation (VP) in miles per second is related to the phase change by the following relationship:

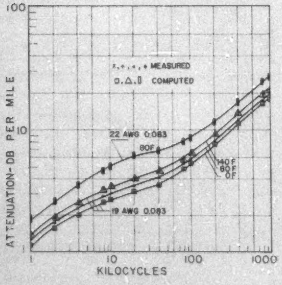

Fig. 6. Attenuation in db per mile versus frequency

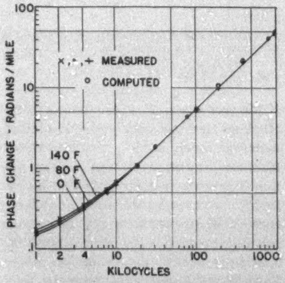

Fig. 7. Phase change versus frequency for 19 Awg 0.083 cable

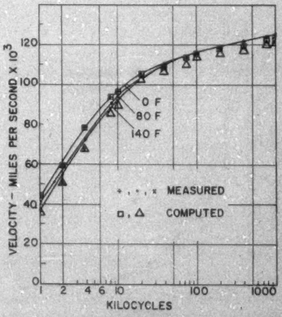

Fig. 8. Velocity versus frequency for 19 Awg 0.083 cable

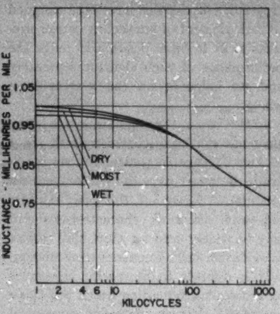

Fig. 9. Inductance per mile versus frequency for dry, moist, and wet 19 Awg 0.083 cable

$$VP = \omega/\beta = 6.283\,f/\beta \qquad (5)$$

where

f = frequency, kc
β = phase change, radians per mile

The phase change and the velocity do not vary significantly with temperature. The measured values of the velocity for the 19 Awg 0.083 cable are given in Fig. 8 along with the velocities computed from cable dimensions at 0 F and 140 F, and the measured values for the 19 Awg 0.066 and 22 Awg 0.083 cables are given in Table I along with the values computed from cable dimensions.

EFFECTS OF MOISTURE ON CABLE PARAMETERS

Moisture, upon entering a polyethylene-insulated telephone cable, may not render it inoperative, but does modify its transmission parameters. A study was made of the transmission parameters of the 100-pair 19 Awg 0.083 cable completely filled with water. The cable parameters were first measured on the cable as received from the factory. The cable was then completely flushed for 24 hours with tap water, having a conductivity of about 70 μmho-centimeters at 1 kc and 77 F, and allowed to remain filled with the flushing water. After the parameters were determined with the cable filled with water, the water was allowed to drains out by uspending the cable in a vertical position for several hours. Immediately following this, the parameters were measured again while the cable was still moist. These latter measurements were completed within 6 hours after cable was drained. The cable was then dried again for several days by pumping dry nitrogen through it. The parameters were again measured and found to be exactly the same as those previously measured when the cable was in the "as received" condition. All measurements were made at room temperature which was within the range of 75 to 85 F. The results are given in Figs. 9–14.

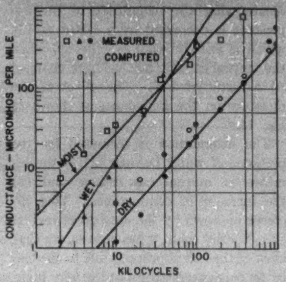

Fig. 10. Conductance per mile versus frequency for dry, moist, and wet 19 Awg 0.083 cable

EFFECTS OF MOISTURE ON PRIMARY PARAMETERS

The results indicate that the water has virtually no effect on the series resistance, as would be anticipated, and no effect on the series inductance except perhaps in the 1–5-kc range as may be seen in Fig. 9 where the inductance is slightly lower wet than dry. This is because at these low frequencies the water has sufficient conductivity so that the cable pair acts somewhat as if it were a twin coaxial. At higher frequencies it does not act in this manner.

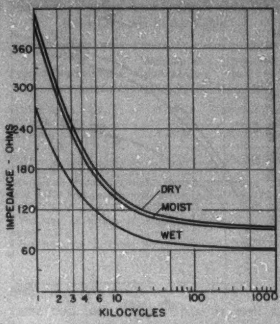

Fig. 11. Characteristic impedance, magnitude versus frequency for dry, moist, and wet 19 Awg 0.083 cable

The mutual capacitance of the wet cable was found to be 0.186 μf per mile which is 2.25 times as high as that of the dry cable which indicates that the dry mutual capacitance is approximately 25% that of the self-capacitance of one insulated conductor. This is to be anticipated because the computed self-capacitance of one insulated conductor is 0.374 μf per mile, and the wet mutual capacitance is equal to one half the self-capacitance (capacitance to water) of a single insulated conductor. This is not the case, however, if the cable has become only moist because in this case the mutual capacitance was found to be 0.090 μf per mile as compared with the dry value of 0.082. The wet and moist mutual capacitance did not change with frequency.

The conductance is increased by the presence of water as indicated in Fig. 10. Reference to equation 4 would indi-

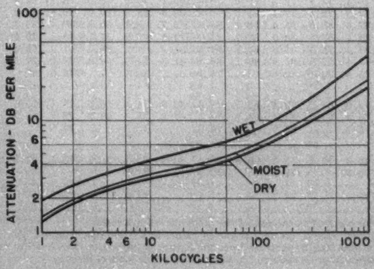

Fig. 12 (left). Attenuation in db per mile versus frequency for dry, moist, and wet 19 Awg 0.083 cable

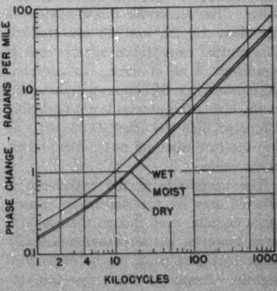

Fig. 13 (right). Phase change versus frequency for dry, moist, and wet 19 Awg 0.083 cable

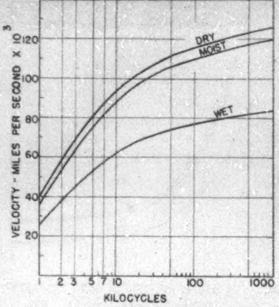

Fig. 14. Velocity versus frequency for dry, moist, and wet 19 Awg 0.083 cable

cate that the conductance would increase by a factor of 2.25 because of the mutual capacitance only. Actually, the wet conductance increases more than this factor especially at frequencies above 10 kc. This is because the water does not have sufficient conductivity to act as a metallic conductor except to some extent at the very lowest frequencies, hence there is a large dielectric loss thus increasing the pf. As indicated previously at low frequencies, the water has sufficient conductivity so that the inductance is decreased. The increase in conductance is accentuated at the highest frequencies where the water behaves as a dielectric material having a high dielectric loss. Since the conductance has so little effect on the transmission properties of the cable, this increase is not important except at very high frequencies.

EFFECTS OF MOISTURE ON SECONDARY PARAMETERS

Although only the mutual capacitance and conductance are significantly changed by the presence of water, all of the secondary parameters—attenuation, impedance, phase shift, and velocity—are significantly changed by the presence of water. The reason for this is obvious if equations 19, 22, and 23 are studied. The mutual capacitance appears and is significant in all of these. In addition, the conductance that appears in these and at the higher frequencies is not negligible compared with the other components as was the case when no water was present in the cable.

The magnitude of the impedance is affected only by the increase in capacitance because, even though the conductance, however, has increased sufficiently to decrease the angle of the impedance slightly. Examination of the data indicates that the magnitude of the impedance is decreased by a factor of 1.5, which is exactly what is expected when the mutual capacitance has been changed by a factor of 2.25. The effect of the moisture on the impedance is shown in Fig. 11.

The attenuation is increased by the presence of water because of (1) the increase of mutual capacitance and (2) the increase of conductance. This increase is shown by the data given in Fig. 12. For dry cable, it has been shown that most of the attenutation is due to the loss in the conductors except at the very highest frequencies. This is not true when water is in the cable.

The phase change and the velocity are both affected slightly in so far as slight amounts of moisture in the cable are concerned; however, in the case of the wet cable, both of these parameters are significantly affected. This may be seen clearly from Figs. 13 and 14.

Crosstalk

Crosstalk and noise currents in telephone circuits are contributed by many sources. In addition to currents flowing through unbalances of cable pairs, there are secondary inductions from inside plant at exchange offices, crosstalk in repeaters, voltages induced by open wires, and so on. Accordingly, filters, balancing, compandors, and other means are used to suppress the effect of crosstalk and noise currents. Target values of minimum crosstalk coupling loss have been assigned to each element of paralleling carrier systems so as to be in position to judge the performance of each element separately and its influence on the system as a whole.

In this paper, the crosstalk in one of the elements will be discussed, namely, in a 19 Awg 0.083 cable. Although not specifically designed as a toll cable from an attenuation viewpoint, this cable exhibits toll grade crosstalk characteristics and may be widely used for short-haul carrier as well as for voice-frequency transmission.

It is difficult to set specific objectives for crosstalk attenuation which this cable must fulfill. It is a matter of economical balance between cable cost and the costs of carrier systems including means employed to improve the over-all performance of the system. Therefore, the crosstalk characteristics of a modern polyethylene-insulated cable will be presented and for reference only some of the figures of crosstalk attenuation found on cables presently in use on carrier services will be quoted.

Some published data show[8] that in paper cables the rms value of far-end crosstalk coupling loss in a mile of quadded cable consisting of 37 quads (excluding strong couplings between pairs within a quad) has been found to be 75 db (decibels) at 165 kc. This high level of crosstalk loss permitted the use of quadded cables in lengths up to 200 miles without pair balancing, for *N1* type carrier designed to prevent near-end crosstalk

All units rms	1200									76.9	
Rms in a mile† of cable		73.4		75.7		74.4		74.9		74.5	

* The rms value is the number of db corresponding to the rms of the crosstalk voltage ratios.

† All crosstalk values, except where expressly stated, are the measured values in a 3,000-foot length. To scale these values down to crosstalk in a mile length, subtract from the figures given in the table 2.4 db. This assumes that crosstalk voltages increase in proportion to the square root of the ratio of lengths.

† See footnote 2, Table II.

from being heard. Paired cables of older (not staggered pairs) design were not as good. The rms crosstalk loss was found to be as low as 55 db in a mile. Improved unit-type cables have had much better rms crosstalk loss, namely, 68 db in a mile of 25-pair unit, with rms coupling loss between units about 9 db higher. These are the crosstalk values which will be compared with the values found in the cable under study. Since some carrier systems permit near-end crosstalk to be heard, values of near-end as well as far-end crosstalk coupling loss are presented. Far-end crosstalk was measured as output to output or equal level crosstalk coupling loss.

Measurements of crosstalk can be very much affected by reflections from mismatched terminations, and a special study was conducted to determine whether pairs not under direct test should be left floating or terminated. It was concluded that for suppression of reflections from open ends of pairs, phantoms, and other tertiary circuits, it is best to terminate all pairs and ground their center taps.

Crosstalk energy is transferred from the disturbing to the disturbed circuits by electrostatic or electromagnetic couplings, which are the results of one or another sort of assymetry in the geometrical shape of pairs introduced by the necessity of design and by unavoidable irregularities in manufacture of cable. Some of the theoretical considerations of the mechanism of this transfer of energy by transverse and interaction paths, as well as formulas used in computations, are given in Appendix V.

Measured Crosstalk Coupling Loss

At 150 kc, representative for medium-frequency range, far-end crosstalk was measured on all units of the cable. The results are given in Tables II-IV. Tests were conducted on the basis that similar results are obtained for a given set of two pairs if one is made disturbing and the other disturbed, and vice versa. A limited number of pair combinations was tested to verify this assumption. Strictly speaking, such reciprocity does not exist for far-end crosstalk[8] due to the difference in the tertiary path of the two pairs in question. The magnitude of difference involved was found to be small for the controlling crosstalk combinations and, therefore, only one test per combination of two pairs was performed.

In Tables II–IV the rms values of cross-

talk, that is, the average crosstalk power ratios, are given for every group of pair combinations in a unit, between units and for the cable as a whole. This tabulation purposely includes the values measured in the 3,000-foot length. Values computed for a mile length are given separately. It was intended to treat the summation of crosstalk currents with length of cable separately from the data derived by the direct test.

Computed for a mile length of cable, the rms far-end crosstalk coupling loss at 150 kc was 74.5 db for pair combinations within a unit, 84.3 db and 94.6 db for combinations between adjacent and opposite units, respectively, and 79.8 db for all combinations within the cable.

Far-end and near-end crosstalk coupling loss as a function of frequency in the range from 1 to 1,000 kc was measured in unit 3. This unit was selected as having rms value of crosstalk loss closest to the grand rms of all four units (Table II).

In Tables V and VI, Figs. 15 and 15(A), test data are presented for far-end and in Tables VII and VIII and Figs. 16 and 16(A) for near-end crosstalk coupling loss.

Introduction of 25 different twists in a 25-pair unit eliminated the source of high crosstalk at carrier frequencies between nonadjacent pairs. It can be seen from the tables that the rms crosstalk coupling loss grows with increased separation between pairs. It is worst for adjacent pairs, followed by combination of center to first layer, and so on. This pattern is followed in all units, for their rms as well as for the worst values. This regularity can be utilized for selection, for carrier transmissions,[7] of pair combinations having desired level of crosstalk coupling loss, when not all of the pairs are used for carrier transmission. At voice frequency (1 kc) the rms crosstalk coupling loss for the worst combination, that is, between adjacent pairs, was over 100 db in a 3,000-foot reel, which is much better than values found in exchange area cables originally designed for voice frequency and in use for many years.

The curves of far-end rms crosstalk coupling loss are of regular shape. Strong currents of transverse crosstalk arrive at the far end in phase and the magnitude of resulting currents changes with frequency in a regular fashion. Weaker currents of interaction crosstalk arrive at far end with phase relation changing with frequency. In the individual pair combinations which, due to chance occurrence, have weak transverse coupling, interaction currents influenced the resultant crosstalk thus causing irregularities in shape of curves. Crosstalk currents between pairs linked by strong transverse coupling were influenced by interaction crosstalk to a small degree and curves of crosstalk loss were regular.

At near end, individual crosstalk currents do not arrive in phase and this summation is random. Since there is a multitude of unbalances of a positive and negative sign randomly distributed along the cable, the cancellation or summation of crosstalk currents, each traveling to the near end along a different path length, will depend on the phase shift between currents. As the frequency increases, the distance between unbalances and the length of cable expressed in wavelength changes, causing currents arriving at the near end to add and subtract periodically. Two cases of near-end crosstalk coupling loss between two pairs are shown in Fig. 17 for mixed couplings (adjacencies) and purely inductive coupling of pairs (six separators). Note that the curves are not wavy as long as the cable is electrically short. At 100–300 kc (curve *B*) some couplings are at such a distance from each other that subtraction of currents prevails. At a higher frequency, the distance in wavelength between individual couplings

A—Between adjacent pairs
B—Between pairs having six separators

is changed and periodical summation and subtraction of currents takes place as frequency is increased.

Curves of rms values of near-end crosstalk coupling loss, shown in Figs. 16(A) and 16(B), are wavy in a less pronounced way. If the number of pairs in a sample is increased, the rms curves will become still more regular as shown by a dotted line for pairs with two separators at frequencies of 60–500 kc, plotted with the size of the sample increased four times to include pairs in all units of the cable.

CHANGE OF CROSSTALK WITH FREQUENCY

Measured and Computed

It is of interest to analyze whether measuring crosstalk at one frequency is sufficient for a reasonably accurate prediction of its value in the whole frequency range.

The rms values of crosstalk coupling loss are dominated by the pairs contributing strongest crosstalk currents, on which interaction crosstalk has little effect. It could be expected, therefore, that changes with frequency can be computed using the classical Campbell's formula for crosstalk ratio, equation 40, Appendix V.

It follows from this equation that far-end output to output crosstalk coupling loss expressed in db is

$$F_l = 20 \log_{10}\left[\frac{j\omega C_u Z_o}{8} - \frac{j\omega L_m}{2Z_o}\right] \qquad (6)$$

where

F_l = far-end coupling loss, db
C_u = capacitance unbalance in length l, farads
L_m = mutual inductance in length l, henrys
Z_o = characteristic impedance of the line, ohms

Between far separated pairs, the capacitive coupling is almost screened out by intervening pairs, and the first term of the equation vanishes. The equation becomes

$$F_l = 20 \log_{10} \frac{j\omega L_m}{2Z_o} \qquad (7)$$

and can be applied to pair combinations with three and more separators.

Assuming for a moment that L_m does not change with frequency, the rms value of crosstalk loss at any frequency f_x can be computed from the rms value measured at one frequency f_o only, using the following expression derived from equation 7.

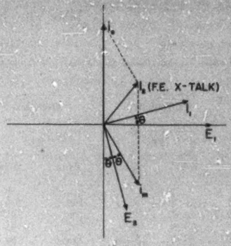

Fig. 18. Vector diagram of far-end crosstalk currents. The terminology used is the same as in Fig. 26. Voltage E_1 and current I_1 in the disturbing circuit induce electromagnetic and electrostatic components I_m and I_c of the crosstalk current I_f which flows toward the far end of the disturbed circuit

$$F_l \text{ at } f_o - F_l \text{ at } f_x = -20 \log_{10} \frac{f_x}{f_o}\frac{|Z_{fo}|}{|Z_{fx}|} \qquad (8)$$

where F_l at $f_o - F_l$ at f_x is the decrement in db of crosstalk coupling loss from the level F_l measured at the frequency f_o, Z_{fx} and Z_{fo} are characteristic impedances at frequencies f_x and f_o, where f_o and f_x, are in kc.

To the values so computed, a correction should be applied to take into account the change of L_m with frequency. As was shown by Hunter and Booth[8] mutual inductance, where affected by combined skin and proximity effects, is a complex quantity $L_m = L_{ma} + jL_{mb}$, which in cables of comparable size, decreases with frequency. L_{ma} drops at 300 kc to about 78% of the value measured at 10 kc and L_{mb}, insignificant at 10 kc, reaches its maximum of 13% of corresponding L_{ma} at 57 kc, decreasing at higher frequencies. Expressed in db, neglecting phase angle, this correction is shown in Table IX.

For example, equation 8 was used to compute the decrease of rms crosstalk coupling loss from rms value measured at 10 kc for pairs with four separators. The results are given in Table IX. It can be seen that after corrections for changes in L_m are introduced, the difference between measured and computed values is less than 0.5 db.

For pairs coupled by both capacitance and inductance this relation is more complex. At 1 kc the second term of equation 6 practically vanishes. As frequency increases, the resultant crosstalk currents will depend on the relative magnitudes of C_u and L_m and on the magnitude and angle θ of the characteristic impedance since the currents subtract vectorially as shown on Fig. 18.

To take into account all the factors, it

is necessary to know the ratio of L_m to C_u, as will be shown in the section on capacitance unbalance. For an approximate computation, equation 8 can be used; it is advisable, however, to make the reference test of crosstalk losses at frequencies above 50 kc, at which Z_o and θ approach constant values as is indicated in Fig. 5 and inductive currents predominate. An example of the application of equation 8 to pairs having capacitive and inductive coupling is given in Table X. Measured values are taken from Fig. 15.

In the computation of changes with frequency of near-end rms crosstalk coupling loss, it should be taken into consideration that capacitive and inductive crosstalk currents tend to add instead of subtract and that they are attenuated on their way back to the near end.

It follows from equations 42 and 43 of Appendix V that near-end crosstalk coupling loss expressed in db is

$$N_l = 20 \log_{10} \left[\frac{j\omega C_u Z_o}{8} + \frac{j\omega L_m}{2Z_o} \right] \frac{1}{\sqrt{n}} \times \sqrt{\frac{1-e^{-4\alpha l}}{4\alpha\Delta}} \qquad (9)$$

where $\Delta n = l$, l is cable length in miles, and n is selected to be large enough so that phase shift and attenuation in the length Δ can be neglected ($\Delta = 20$–30 feet). N_l is near-end crosstalk coupling loss in length l in db, α is attenuation of line in nepers per mile, C_u and L_m are capacitance unbalance in farads and mutual inductance in henrys in the length l. Equation 9 can be transformed, assuming inductive couplings, in a similar way as equation 8 for computation of the decrease of coupling loss relative to the loss measured at a chosen frequency.

$$N_l \text{ at } f_o - N_l \text{ at } f_x = -20 \log_{10} \frac{f_x}{f_o} \frac{|Z_{fo}|}{|Z_{fx}|} \times \sqrt{\frac{\alpha_o}{\alpha_x}} \sqrt{\frac{1-e^{-4\alpha_o l}}{1-e^{-4\alpha_x l}}} \qquad (10)$$

where l is 0.57 miles and α_o and α_x are attenuations in nepers per mile at frequencies f_o and f_x. Other symbols are as given in equations 8 and 9.

Due to the waviness of near-end crosstalk loss curves, the prediction of changes with frequency of near-end crosstalk coupling loss is not as reliable as the prediction of far-end crosstalk. It will depend, first of all, on whether crosstalk has been measured at a frequency at which the curve of crosstalk is wavy, which can cause the reference point, that is, the measured value (see Fig. 16) to shift considerably from its true position. Most favorable conditions will be established if the frequency at which crosstalk is measured is chosen low enough so that the cable is not longer than 1/4 wavelength (to avoid waviness of curves) and high enough to make inductive currents predominate; 50–70 kc seem to be appropriate for this test.

Using equation 10, changes of rms coupling losses were computed from the measured at 50 kc and compared with changes of crosstalk as given in Fig. 16, with the waviness of the curves smoothed out. The data are given in Table XI.

It can be seen that the deviation of the computed values from the measured is greater for near-end than for far-end crosstalk.

It appears from the quoted examples that crosstalk coupling loss can be predicted for the whole carrier frequency range from a test performed at only one frequency, with good accuracy at far-end and with reasonable approximation at near end.

CAPACITANCE UNBALANCE AS AN INDEX OF CROSSTALK

It is common to measure capacitance unbalance in order to determine the value of crosstalk within the voice-frequency range. It will be useful to analyze whether this test can be regarded as a reliable index of inductance unbalance and, by it, an index of crosstalk at carrier frequency as well.

At voice frequency (1 kc), the rms capacitive crosstalk currents between adjacent pairs are ten times greater than the rms inductive currents. Since these currents add or subtract vectorially at an angle of about 86 degrees, the resultant vector differs from capacitive current by a fraction of 1% only. The inductive component of crosstalk currents can be, therefore, neglected and it is enough to perform a simple test of capacitance unbalance to determine crosstalk characteristic of a cable at voice frequency.

The values of capacitance unbalance measured between pairs of unit 3 are given in Table XII. The crosstalk coupling loss at 1 kc was computed from rms values of capacitance unbalance employing equation 6 and neglecting the term for mutual inductance. For comparison, values of near-end crosstalk measured at 1 kc are given in the same table.

It can be seen that for the combinations of pairs having capacitive couplings, the rms values of crosstalk are practically the same, whether measured as capacitance unbalance or as crosstalk coupling loss. For pairs with many separators, the relation does not hold since inductive coupling alone is causing crosstalk, the absolute value of which is, however, negligible in the order of a fraction of one crosstalk unit (over 120 db).

Table XIII. Equivalent Mutual Inductance, Factor $m = \frac{L_m}{C_u} \frac{\mu\mu h}{\mu\mu f}$

	Pairs Combination		Two Separators
	Adjacent	Alternate	
Unit 1	6.1	5.7	9.4
Unit 2	4.7	6.1	9.1
Unit 3	6.0	6.9	7.5
Unit 4	6.5	6.1	7.4
Grand Rms, four units	5.9	6.3	8.0
Two cables spliced, unit 3	5.4	6.8	7.7

Note: Both L_m and m decrease with frequency by factors 0.90, 0.83, 0.82, and 0.78 at 50, 100, 150, and from 300 kc up, respectively.

As frequency is increased, the inductive components of crosstalk increase rapidly. At 10 kc (for adjacent pairs) the magnitudes of capacitive and inductive currents become equal and at 1,000 kc inductive currents are roughly twice as high as capacitive. For nonadjacent pairs, the ratio increases in favor of inductive currents. Direct tests of crosstalk or of mutual inductance are relatively complicated, and a method was sought to correlate capacitance unbalance with mutual inductance so that by testing one quantity, sufficient information can be derived to estimate another.

It was found that such correlation does exist in cables in which conductors are insulated with accurately applied polyethylene. In rms values, there is about 6 mμh (millimicrohenry) of mutual inductance per 1 μμf (micromicrofarad) of capacitance unbalance between adjacent pairs. This can be understood considering the source of unbalances. If pairs were not twisted then a very strong inductive and capacitive coupling would exist between them due to their proximity in the cable. By transposition (pair twisting) those strong couplings are changed into a multitude of small couplings of opposite signs, which mutually almost cancel, and the minute residues left are called capacitance unbalance and mutual inductance. These residues amount to a fraction of 1% of the original inductive and capacitive couplings. If twisting of pairs is inaccurate, both unbalances will be affected.

Based on this premise, an rms "equivalent" mutual inductance has been computed from values of rms crosstalk loss measured at 1 kc and 1,000 kc using equation 11, assuming that L_m is zero at 1 kc and $\theta = 0$ at 1,000 kc. Since mutual inductance L_m changes with frequency, as previously stated, the values of L_m computed from crosstalk at 1,000 kc have been corrected so that the values of factor m given in Table XIII refer to an equivalent L_m at 1 kc.

A correlation can be seen between rms values of capacitance unbalance and mutual inductance. For a particular pair combination the ratio m, that is, the number of units of mutual inductance per one unit of capacitance unbalance, varies not more than 20% or, in crosstalk inductive currents ±1.9 db from the grand rms of the particular type of pair combinations. As the separation between pairs increases the ratio of L_m/C_u increases also, showing the shielding effect of intervening pairs by relative reduction of capacitance unbalance C_u.

Once the ratio between the equivalent L_m and C_u is established, the crosstalk coupling loss can be computed from equation 11 substituting mC_u for L_m. This is applicable for pairs with measurable capacitance unbalance (adjacent, alternate, and pairs with two separators). For other pair combinations, crosstalk loss has to be estimated from the cable design and quality of pair twisting, indicated by the capacitance unbalance test. The applicable equations are given in the following. The rms far-end crosstalk current ratio expressed in crosstalk units (CU) is

$$F_{cu}' = \frac{j\omega C_u Z_o}{8 \times 10^6} - \frac{j\omega L_m}{2Z_o \times 10^3}$$

$$= \frac{j\omega C_u}{8 \times 10^6}\left[Z_o - \frac{4m10^3}{Z_o}\right] = C_u \times P_m \quad (11)$$

where

F_{cu}' = rms crosstalk current ratio, C_u
L_m = rms mutual inductance, mμh, at frequency of test
C_u = rms capacitance unbalance, μμf
Z_o = characteristic impedance, ohms
m and corrections for frequency are given in Table XIII

The value of P_m has been computed for various values of m for 19 Awg 0.083 cables with the two terms in parenthesis of equation 11 added vectorially and corrections introduced for changes of L_m with frequency. Values of P_m are given in Fig. 19.

Equation 11 can be used in conjunction with Table XIII and Fig. 19 to compute rms far-end crosstalk coupling loss at any frequency when the value of m is known and capacitance unbalance C_u is measured. Expressed in db, far-end crosstalk coupling loss is equal to $20 \log_{10} F_{cu}' - 120$.

Near-end crosstalk current ratio in CU can be computed from equation 11 by changing the minus sign to plus and allowing for attenuation at the near end; however, due to the nature of near-end crosstalk, the estimate will be less accurate than the estimate of far-end crosstalk.

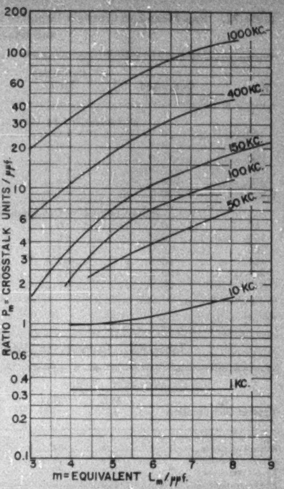

Fig. 19. Crosstalk units per 1 μμf of capacitance unbalance for various values of m (equation 11)

The method discussed for approximating crosstalk from the measured capacitance unbalance is not suggested as a substitute for direct measurements of crosstalk. It is intended only to draw attention to the fact that capacitance unbalance in a general way is an index of symmetry and crosstalk characteristics of cable at carrier frequencies and to show that rms crosstalk coupling loss in a range of 1–1,000 kc can be estimated from capacitance unbalance with an accuracy of a few db, after the values of m are established for a particular cable design.

The ratio $L_m/C_u = m$, given in Table XIII, has been established for the design and manufacturing methods employed to produce the polyethylene-insulated cable tested. If the design is changed, for instance, regularity of extrusion of conductors, type of twisting, number of pair twists, and so on, then the ratio of equivalent $L_m/C_u = m$ will change also.

The rms value of m for any design of 19 Awg 0.083 cable can be established using expression 11 and Fig. 19 from a test of capacitance unbalance at 1 kc and of cross-talk coupling loss at any convenient carrier frequency.

It is expected that for 22 Awg 0.083 cables the same relation will be valid since mutual capacitance and inductance of circuits are practically the same as for 19 Awg 0.083 type of cable. For 19 Awg 0.066 cables, the ratio L_m/C_u should increase due to the reduction in mutual capacitance and increase in inductance of circuits. The absolute value of equivalent mutual inductance should not increase, however, by more than 1.5 db since the absolute value of inductance of circuits is increased by 20% but the separation between pairs is also increased. Inductive crosstalk currents will not increase, however, due to compensating increase in Z_0.

SUMMATION OF CROSSTALK WITH LENGTH

To check whether the rule of random summation of currents with increased length of cable will hold when cables are straight-spliced, two reel lengths were spliced and tested. On purpose, most unfavorable conditions were arranged. Spliced units were originally paired, stranded, and cabled in one continuous run. If, in the process of manufacture, some of the elements (diameter of conductors, uneven twisting) were systematic then this should show up in the crosstalk tests on pairs spliced color to color. The results of the test are given in Table XIV.

It can be seen that the levels of crosstalk loss were different in the two reels. When rms values of crosstalk currents were added $(F_{12}'=\sqrt{F_1'+F_2'})$, it was found that for the adjacent pairs, that is, for the controlling pair combinations, the measured value was somewhat better than would have been expected from the random summation of currents. A deviation of the same magnitude but of an opposite sign can be seen for far separated pairs between which the crosstalk loss is roughly 20 db higher than between adjacent pairs. The deviations were small, within possible test error, particularly at 1,000 kc. No indications were found in this limited test that the rule of random summation of currents may not apply for straight-spliced cables.

Applying the principle of random summation, the rms values of crosstalk coupling loss given in the tables and graphs for a 3,000-foot length of cable can be converted to other lengths using equations 41 and 43 of Appendix V.

FAR-END CROSSTALK

$$F_l=(F_o-2.4)-10\log_{10} n \qquad (12)$$

where

F_l = crosstalk in db for chosen characteristic (pairs combinations, unit or cable) in n miles of cable
F_o = crosstalk in db read on Tables II–VI or Figs. 15(A) and 15(B) for 3,000-foot length of cable (−2.4 db is added to convert crosstalk F_o into crosstalk in a mile length)
n = miles

NEAR-END CROSSTALK

$$N_l=N_o-20\log_{10}\sqrt{\frac{1-e^{-4\alpha l}}{1-e^{-4\alpha l_0}}}=N_o-D_o \qquad (13)$$

where

N_o = value of crosstalk in a 3,000-foot length of cable given in Figs. 16(A) and 16(B) and Tables VII and VIII
α = attenuation, nepers per mile
l = length, miles
l_0 = 0.57 mile (3,000 feet)
N_l = near-end crosstalk in length l, db

The second term of equation 13, D_o, is given in Fig. 20.

Shield Parameters

The Alpeth sheath of the plastic telephone cable, in addition to providing a protective outer covering for mechanical and handling purposes, also serves to reduce interference from power lines and interference from atmospheric discharges at carrier frequencies. The sheath also provides a low-resistance path so that lightning currents in the vicinity do not build up excessive voltages along the shield and cause dielectric breakdown of the underlying insulation. It will be indicated later that it is desirable to have a low shield resistance (or impedance).

One type of voltage, induced in the cable at voice frequencies from external sources, is due to magnetic induction and is proportional to the magnitude of the harmonics of the power currents in the disturbing circuit. This voltage is induced longitudinally along the cable and is reduced to zero if the shield resistance is zero (see Appendix VI) and the shield is grounded at both ends through ground connections having zero resistance. This condition, of course, is never achieved in practice because the shield and the ground connections both have resistance. Because the two wires forming a telephone pair are twisted and are close together, practically no differential voltage is induced directly between the wires themselves to produce noise currents. However, there is an induced voltage between the two wires of a pair and ground, or along the two wires in parallel, which causes noise current in the pairs due to cable pair unbalances.

The second type of induced voltage is proportional to the voltages of the power circuit and is called electric induction. This type of induction appears between the core and ground if the shield is floating and may be easily eliminated by grounding the shield at sufficiently short intervals. The discussion of shield factors of the cable assumes that this type of induction has been eliminated by proper grounding.

SHIELD FACTOR FOR MAGNETIC INDUCTION

The shield factor may be defined as the ratio of the induced voltage along the cable core when the shield is present (assuming an electrically short length with perfect grounds at both ends) to the induced voltage when the shield is absent. Good shielding is obtained when the shield factor is low. The shield factor as explained in Appendix VI may be expressed as follows:

$$S_f=\frac{Z_{11}-Z_{12}}{Z_{11}} \qquad (14)$$

where

* For cable 20 feet above ground and computed values are based on equations 14 to 17 inclusive.

† ρ_g is the earth resistivity in meter-ohms.

‡ Computed values for the helical-shield are made on the basis that the shield is applied as a fold having the same d-c resistance as the helical tape shield for which measured values are given.

S_f = shield factor
Z_{11} = ground return self-impedance of the shield, ohms per mile
Z_{12} = ground return mutual impedance between the shield and the core of the cable, in ohms per mile

The term $(Z_{11}-Z_{12})$ is the leakage impedance between the shield and the shielded conductors. It also is called the transfer imedance or surface transfer impedance in ohms per mile and is designated as Z_{ab}. Therefore, equation 14 may be rewritten as:

$$S_f=\frac{Z_{ab}}{Z_{11}} \tag{14A}$$

The calculation of shield factor is not practical at higher frequencies since it assumes grounds at intervals which are short as compared with the wavelength. For example, at 300 kc, grounds 100 feet apart would have an electrical length of about 1/20 wavelength (18 degrees) which is about the maximum length for an electrically short line. Computed and measured shield factors are tabulated in Table XV for a cable having a folded aluminum shield with a measured and calculated d-c resistance of 2.25 and 2.26 ohms per mile, respectively, and a cable having the same core but having two helically applied aluminum tapes 1.5 inches by 0.005 inch with a 2.6-inch pitch and a measured and calculated d-c resistance of 8.79 and 8.74 ohms per mile, respectively. The d-c resistance of the folded shield was calculated as if it were a tube and the helical tape was calculated assuming no contact between turns. The diameter under the shield for each cable was 1.30 inches. In order to determine the shield factor it is necessary to calculate first the surface transfer impedance and next the ground return self-impedance of the shield.

SURFACE TRANSFER IMPEDANCE OF THE SHIELD

The surface transfer impedance (Z_{ab}) which appears in equation 14(A) is the ratio of the voltage induced along the inside of the shield to the current flowing in the shield. The values are usually converted to volts per mile for one ampere of disturbing current flowing in the shield. It is helpful to present the data in decibels above or below one ohm per mile (i.e. 20 $\log_{10}|Z_{ab}|$ where $|Z_{ab}|$ is ohms per mile). The magnitude of the surface transfer impedance for a shield consisting of a tube may be calculated from the following formula developed by Schelkunoff:[9]

$$|Z_{ab}|=R_{dc}'\left[\frac{u}{\sqrt{\cosh u-\cos u}}\right] \tag{15}$$

where

R_{dc}' = shield d-c resistance, ohms per mile
$u=18.97t_s\sqrt{f}$
t_s = thickness of the shield, inches
f = frequency, in kc, for aluminum tubes

If the shield consists of helically applied tapes, this formula does not hold because the currents spiral around the core. This is particularly true if the shielding tape is made of aluminum because of the high contact resistance between the surfaces of the aluminum tape at their overlaps.

The surface transfer impedance was measured using a method similar to that described by Gooding and Slade.[10] The conductors were all connected and served

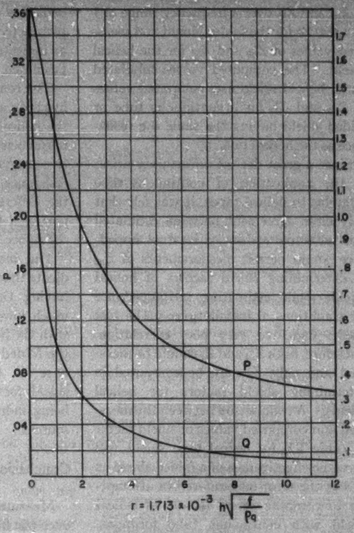
The reactive component was too small to measure on available equipment at frequencies below 20 kc for the folded shield; consequently, this component is tabulated as zero.

as the return path. (A diagram is shown in Fig. 23(A) which gives the measuring circuit employed.) A coaxial cable having a solid aluminum sheath was used to establish the accuracy of the circuit because such a configuration permits Z_{ab} to be accurately calculated using equation 15. The results obtained for folded and helical shields are shown in Table XVI, columns 2 and 7, for measurements over a frequency range of 1 kc to 1,000 kc. Computed values of Z_{ab} employing equation 15 with computed d-c resistance for the folded shield cable are also tabulated in Table XVI, column 3. The tabulated results clearly show that the computed and measured values of surfaces transfer impedance for a folded shield are in close agreement. This is expected since a folded shield behaves as a continuous tube for normal transmission. However, the helical shield deviated markedly from the computed values. These computed values are not tabulated.

Fig. 21. Functions P and Q for use in equation 16



GROUND RETURN SELF-IMPEDANCE OF THE SHIELD

The ground return self-impedance of the shield as shown in equation 14(A) is equal to the sum of an internal impedance (Z_i) and an external impedance (Z_e). The external impedance (Z_e) includes the effect of the magnetic flux in the earth and between the surface of the shield (if aerial) and the surface of the earth and is, therefore, the external series self-impedance of a tube or round conductor above earth with perfect ground connections. Z_e is quite difficult to measure and is therefore estimated. Z_i is the internal or intrinsic impedance of a tube with an external return path and is sometimes referred to as Z_{bb} and is nearly equal to Z_{aa} for large diameters and thin shields. The latter impedance (Z_{aa}) is the internal impedance of a tube with an internal return path. Since it is simpler to measure, it was measured instead of Z_{bb}.

The internal impedance (Z_{aa}) was measured employing a method similar to that used for measuring Z_{ab} except that both the phase and magnitude of the current and voltage along the outside of the shield were measured instead of magnitudes only of the current on the outside of the shield and voltage on the inside of the shield. It is necessary to know the phase angle of the internal impedance in order to compute the denominator of the shield factor. (A diagram of the test circuit is shown in Fig. 23(B).) Since there are innumerable conditions in the field (i.e., ground resistivity, cable height, etc.), it was felt that the computed external impedance for a fixed cable height of 20 feet and several ground resistivities would approximate field conditions. This may be derived from the following equations due to Carson[11] for Z_{11} and to Schelkunoff[9] for Z_i:

$$Z_{11}=Z_i+j7.41\omega\times10^{-4}\log_{10}24h/b+6.44\omega(P+jQ)\times10^{-4}\text{ ohms per mile}\qquad(16)$$

where

$$Z_e=j7.41\omega\times10^{-4}\log_{10}24\,h/b+6.44\omega(P+jQ)\times10^{-4}\qquad(16\text{A})$$

where Z_i (or Z_{bb}) is given by:

$$Z_{bb}=Z_i=R_{dc}'\left[\frac{u}{2}\frac{(\sinh u+\sin u)+j(\sinh u-\sin u)}{\cosh u-\cos u}+\frac{t_s}{2b}\right]\text{ ohms per mile}\qquad(17)$$

where

h = distance of shield above ground, feet
b = outside radius of shield, inches
ρ = earth resistivity, meter-ohms
t_s, u, f = same as given in equation 15
$\omega=2\pi f$
P, Q = special functions given in Fig. 21 for argument $r=1.713\times10^{-3}h\sqrt{f/\rho_g}$

The first two terms on the right-hand side of equation 16 represent the series impedance of a shield with ground return if the ground is a perfect conductor. The last term represents the effect of finite conductivity of the ground. The last two terms are the external impedance (Z_e) which is due to fluxes caused by current in the shield and return current in the earth. This flux exists in the earth and between the surface of the earth and surface of the shield. The magnetic flux pattern is transverse to the axis in cylinders and helical in helices. The external transverse component of the helical flux is much more important than the external axial component and, therefore, the external field (per ampere) is much the same for cylindrical shields and for practical forms of helical shields. The external part (Z_e) of the self-impedance (Z_{11}) may be calculated from equation 16(A) for a cylindrical shield and estimated for a helical shield. The height of 20 feet mentioned is not critical since, in the practical case, the image conductor for computing Z_e is quite deep and Z_e changes slowly with the cable height. The calculated values of Z_e for ρ_g of 10 are 1.30+j15.6 at 1 kc and 284+j12,250 at 1,000 kc; these compare to values of internal impedance (Z_i) of 8.76+j2.00 and 709+j616 for the helical tape shield and internal impedance of 2.14+j0 and 4.69+j4.44 for the folded tape shield, respectively. All values are given in ohms per mile.

Once the self-impedance (Z_{11}) is determined for a given ground resistivity, the shield factor may then be determined for this value using equation 14. Table XV gives shield factors determined by computing the external impedance for ρ_g equal to 10, 100, and 1,000 meter-ohms, and both measured and computed values of Z_{ab} and Z_{bb} over a frequency range of 1 to 1,000 kc for the folded shield and measured values of Z_{ab} and Z_{bb} for the helical shield. The computed values tabulated under helical shield uses computed values of Z_{ab} and Z_{bb} for a continuous tube or folded shield having the same d-c resistance as the helical tape.

Since a great deal of uncertainty arises in the application of continuous tube formulas to helical tapes, it was felt that only close agreement between estimated and measured values of internal impedance would permit measurements of Z_{ab} in determining shield factors of helical shields while estimating self-impedance for conditions of installations. The test results indicated very poor correlation. Therefore, both Z_{ab} and Z_i should be measured and only Z_e may be computed in determining shield factors for helical shields. A comparison between the measured and computed values of shield factor in Table XV for helical tape shield will show the effectiveness of a folded shield as well as the error encountered in attempting to compute shield factors of helical shield with continuous tube formulas. In using the data presented in this table the relative shield factors are applicable only to electrically short lines. As previously indicated, the comparisons shown are not valid unless this is the case and may be somewhat different in actual cases where grounding of the shield is not frequent enough to ground at electrically short distances.

Shield-Core Impedance (Surge Impedance)

The shield to core impedance of the cable (between the shield and all the pairs) was measured in order to determine the impedance offered to lightning surges. Atmospheric discharges, i.e., lightning currents, in the vicinity of the cable cause currents to flow along the shield and if the resistance of the shield is low the voltage drop along the shield will be low. The longitudinal current along the shield produces a voltage inside the shield which in extreme cases, may cause breakdown to core and in other cases cause noise currents to flow along the cable pairs if there is an unbalance to ground which is normally the case. The amount of current that will flow will be determined, therefore, by this shield to core impedance of the cable and the unbalance.

In order to measure this impedance, the cable was regarded as a coaxial cable having all pairs connected as an inner conductor and the shield as outer conductor. The impedance was determined by measuring the short- and open-circuit impedances on the same bridge as used for parameter measurements and calculated as indicated previously. The results are tabulated in Table XVI.

The results show that the folded shield has only a slightly lower impedance than the helically applied shield at the higher frequencies. This is because the inductive reactance is much lower than the a-c resistance. However, at low frequencies, the difference in the impedance is proportional to the square root of the shield resistance.

The measurements on the shield indicate that the cable with the folded shield having the lower d-c resistance has a much lower shield factor than the cable with the helical shield; this is true even if the folded shield has the same d-c resistance as the helical shield. This low shield factor will result in less voltage being induced in the core from external sources.

Conclusions

Measurements have been conducted over the frequency range of 1 kc to 1,000 kc and a temperature range of 0 F to 140 F to establish the primary and secondary parameters of a typical multipair polyethylene-insulated Alpeth-sheathed telephone cable. Crosstalk properties over the same frequency range have been measured. Formulas have been suggested which permit calculation of the parameters from cable dimensions with a reasonable degree of accuracy. The extent of the effects of immersion of the cable core in water or of moisture contamination on the parameters are presented.

It is indicated that from the measurements of crosstalk at one frequency the crosstalk at other carrier frequencies can be estimated with good accuracy for far-end and with fair accuracy for near-end crosstalk coupling loss. A correlation between capacitance unbalance and crosstalk at higher frequencies for pairs having capacitive coupling is indicated and the ratio between capacitance unbalance and equivalent mutual inductance given. The change of crosstalk coupling loss as a function of cable length has been explored and a method of computation indicated.

The shield parameters have been measured at room temperature over the frequency range of 1 kc to 1,000 kc and these indicate the advantages of using a cable with a folded or tubular low-resistance metallic shield.

Appendix I. Test Equipment

The primary parameters were measured using a Siemens and Halske impedance-measuring bridge, type *Rel 3 R 217 P(n)*. The open-circuit admittance and the short-circuit impedance of the cable pair under test were measured at the frequency and temperature applicable. Such measurements were made at frequencies from 1 to 1,000 kc at temperatures from 0 F to 140 F in steps of 20 degrees. For measuring the open-circuit admittance the bridge is connected as a Wheatstone bridge modified for a-c applications as devised by Wien (specimen and standard in adjacent bridge arms); for measuring the short-circuit impedance the bridge is connected as a Maxwell bridge (specimen and standard in opposite arms). Various checks against laboratory standards were made with the bridge and it was found to be accurate within the following manufacturers' guaranteed values: for open-circuit admittance the accuracy is ±1% for capacitance and ±1% for conductance for frequencies below 700 kc and ±2% for conductance for frequencies above 700 kc; for short-circuit impedance the accuracy is ±1% for both resistance and inductance.

The oscillator used in conjunction with the bridge was a General Radio Standard Signal Generator type *1001-A* in the frequency range 400 kc to 1,000 kc and a Hewlett-Packard Audio Frequency Oscillator

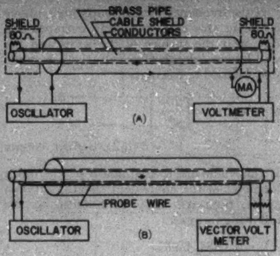

Fig. 23. Schematic diagram for circuit used in measuring the surface transfer impedance (Z_{ab}) of the shield (A) and the internal impedance (Z_i) of the shield (B)

model *233A* in the frequency range 1 kc to 400 kc. Two detectors were employed: the Rhode and Schwarz Tunable indicating amplifier type *UBM* and the Hewlett-Packard Vacuum Tube Voltmeter model *400 H*.

Crosstalk was measured by a comparison method. The voltages in the disturbed and disturbing circuits were compared using a standard attenuator connected to the disturbing line. In measuring, the attenuator was adjusted until the same voltages were read by the detector when switched from the disturbed circuit to the attenuator. This eliminated the need for calibration or for corrections of readings of the disturbing and disturbed voltage levels. To provide terminations for phantom and other tertiary circuits, the center taps of terminations on all pairs in the cable were grounded as well as the center tap of the balanced attenuator. The oscillator, preamplifier, and detector were of the balanced type, not grounded at the center tap. The schematic diagram of the connections for measurement of far-end output to output crosstalk is given in Fig. 22(A) and for measurement of crosstalk at the near end is given in Fig. 22(B).

As shown in the circuit diagrams (Fig. 22), one end of the disturbing pair and both ends of the disturbed pair were terminated into precision networks. The maximum deviation of impedances of these networks (real and imaginary) from corresponding characteristic impedance of a typical pair at frequencies between 1 kc and 1,000 kc was less than ±2%. All other pairs were terminated in pure resistances.

The attenuator used was type *Rel 3D 24*, Siemens and Halske, with a range of 160 db at frequencies 1–20 kc and 130 db at 20–1,000 kc. Checked against laboratory standards, the accuracy of the attenuator was established to be within 0.2 db. The oscillator, Siemens and Halske *Rel W 317a*, has a maximum frequency error of ±0.2% up to 100 kc and 0.5% at frequencies above 100 kc. Preamplifier and superheterodyne receiver, Siemens and Halske *Rel 3U 42* and *Rel 3U 412a*, were sensitive to 0.3-microvolt signals and the sensitivity was used when extraneous noise voltages were filtered by using 10-cps (cycles per second) or 100-cps bandwidths when measuring high attenuations (above 120 db). At frequencies above 300 kc and losses below 75 db, for convenience a vacuum-tube voltmeter, Hewlett and Packard type *400H*, was used as a detector.

The measuring circuits employed for shielding studies are shown in Fig. 23.

Appendix. II Cable Parameter Relations

The electrical characteristics of a balanced cable pair are given by the following well-known[13] relations:

$$\gamma=\alpha+j\beta=\sqrt{ZY} \text{ propagation coefficient} \quad (18)$$

$$Z_0=\sqrt{Z/Y}=\sqrt{\frac{R+j\omega L}{G+j\omega C}}$$

$$= \text{characteristic impedance} \quad (19)$$

$$Z_0\gamma=Z=R+j\omega L \quad (20)$$

$$\gamma/Z_0=Y=G+j\omega C \quad (21)$$

where

α=attenuation, nepers per mile (db per mile=8.686 X nepers per mile)
β=phase shift, radians per mile
$Z=R+j\omega L$=series impedance, ohms per mile
$Y=G+j\omega C$=parallel admittance, mhos per mile
R=series resistance, ohms per loop mile
L=series inductance, henrys per loop mile
G=parallel conductance, mhos per mile
C=mutual capacitance, farads per mile
$\omega=2\pi f'$ where f' is the frequency in cps

In equation 18, $\gamma=\alpha+j\beta$, it may be shown[13] that in terms of the distributed parameters R, L, G, and C:

$$\alpha=\sqrt[4]{(RG-\omega^2LC)^2+(G\omega L+R\omega C)^2}\times \cos\frac{1}{2}\left[\tan^{-1}\frac{G\omega L+R\omega C}{RG-\omega^2LC}\right] \text{ nepers per mile} \quad (22)$$

$$\beta=\sqrt[4]{(RG-\omega^2LC)^2+(G\omega L+R\omega C)^2}\times \sin\frac{1}{2}\left[\tan^{-1}\frac{G\omega L+R\omega C}{RG-\omega^2LC}\right] \text{ radians per mile} \quad (23)$$

At high frequencies equations 22 and 23 may be expressed as:

$$\alpha\cong\frac{1}{2}G\sqrt{L/C}+\frac{1}{2}R\sqrt{C/L} \quad (22A)$$

$$\beta\cong\omega\sqrt{LC} \quad (23A)$$

At low frequencies equations 22 and 23 may be expressed as:

$$\alpha\cong\sqrt{\omega RC/2} \quad (22B)$$

$$\beta\cong\sqrt{\omega RC/2} \quad (23B)$$

In addition to the foregoing, the following well-known relations[13] are useful; these are given in terms of the series and parallel measured parameters for length, l, of the line:

$$Z_{sc}'=R'+j\omega L'=Z_0\tanh\gamma l$$

$$Y_{oc}'=1/Z_{oc}'=G'+j\omega C' =\frac{1}{Z_0\coth\gamma l}=\frac{\tanh\gamma l}{Z_0}$$

Therefore:

$$Z_0=\sqrt{Z_{oc}'Z_{sc}'}=\sqrt{Z_{sc}'/Y_{oc}'} \quad (24)$$

and

$$\tanh\gamma l=\sqrt{Z_{sc}'/Z_{oc}'}=\sqrt{Z_{sc}'Y_{oc}'} \quad (25)$$

where

Z_{sc}'=short-circuit impedance of the pair in ohms for length l
R'=series loop resistance in ohms for length l
L'=series loop inductance in henrys for length l
Y_{oc}'=open-circuit admittance of the pair in mhos for length l
G'=mutual conductance in mhos for length l
C'=mutual capacitance in farads for length l
l=length of line in miles under test

If the short-circuit impedance and open-circuit admittance are measured then the characteristic impedance Z_0 may be calculated from equation 24 and $\tanh \gamma l$ may be calculated from equation 25. Further, if then Z_0 and $\tanh \gamma l$ are known it is merely necessary to determine γ from $\tanh \gamma l$ and then, using equations 20 and 21, determine the primary parameters, R, L, C, and G.

In order to obtain γ, α and β are calculated from the following relationships,[13] letting $\tanh\gamma l=A+jB=D\underline{/\phi}$

$$\tanh 2\alpha l=\frac{2A}{1+A^2+B^2} \quad (26)$$

$$\tan 2\beta l=\frac{2B}{1-(A^2+B^2)} \quad (27)$$

where

$$\tanh\gamma l=D\underline{/\phi} =\sqrt{(R'+j\omega L')(G'+j\omega C')} \quad (28)$$

$$A=D\cos\phi$$

$$B=D\sin\phi$$

From equations 26 and 27 the real functions of the components of γ can be determined and α and β can then be determined from the tables of these real functions and then adjusted to a per-mile basis. This gives γ on a per-mile basis which then is substituted in equations 20 and 21 yielding R, L, C, and G on a per-mile basis.

Appendix III. Calculation of the A-C Resistance of a Pair Having Copper Conductors

The skin effect may be readily calculated by the use of the parameter x and curves of Fig. 24 which has been compiled from complicated exact formulas.[14]

$$x=2.845\sqrt{f/R_{dc}} \quad (29)$$

where f is the frequency in kc and R_{dc} the d-c resistance of the conductors in ohms per loop mile at the temperature under study.

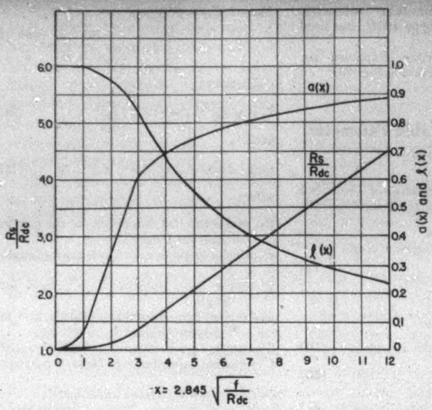

Fig. 24. Functions R_s/R_{dc}, $a(x)$ of equation 30 and $l(x)$ of equations 2 and 2(A) or 35 and 36

The d-c resistance may be calculated from the dimensions of the conductor using conventional formulas taking into account the temperature under study. One or two per cent should be added to this resistance which is an approximation to allow for the added length due to pairing and cabling. Having calculated x from equation 29, the resistance including skin effect is obtained by multiplying ratio R_s/R_{dc} of Fig. 24 for the corresponding x by R_{dc} and obtaining R_s, the a-c resistance including skin effect. The increment due to skin effect, ΔR_s, is equal to $R_{dc}(R_s/R_{dc}-1)$.

The a-c resistance including proximity effect as well as skin effect may be calculated by using the following formula due to Arnold.[15]

$$P=\sqrt{\frac{1}{1-A_0{}^2a(x)}}=\text{proximity factor} \qquad (30)$$

where

$A_0=d/s$
d = diameter of the conductor, inches
s = the center to center spacing of conductors, inches
$a(x)$ = see Fig. 24

(The 19 Awg 0.083, 19 Awg 0.066, and 22 Awg 0.083 cable tested during this program have insulated conductor diameters, or center to center spacing values, of 0.062 inch, 0.081 inch, and 0.045 inch, respectively.)

The approximate relationship, equation 30, has been derived by Arnold based on previous work done by Carson[16] and Dwight[17] and is simpler and can be evaluated in a shorter time than the more complicated and exact formulas developed by the others. Measurements indicate this formula is suitable for use in telephone cables and in the range up to 1,000 kc. Once having the factor P, the a-c resistance, including skin plus proximity effects, is calculated from the following formula:

$$R_{sp}=R_sP \qquad (31)$$

The increment due to proximity effect, ΔR_p, due to presence of the other conductor of the pair is equal to $R_{sp}-R_s$.

The component ΔR_t may be estimated by considering the surrounding pairs to be replaced by a copper tube and utilizing formulas developed by Meyerhoff[18] for losses in a sheath surrounding a pair of conductors. Meyerhoff has developed the following relationship for two wires in a sheath:

$$\Delta R_t=0.1913f'M_{21} \text{ microhm per foot}$$
$$=1.01\times10^{-3}f'M_{21} \text{ ohms per wire mile}$$

$$\Delta R_t=2.02\times10^{-3}f'M_{21} \text{ ohms per mile of a pair} \qquad (32)$$

where

$$M_{21}=4v\left[\frac{0.25}{1+v^2}+\frac{0.01563}{9+v^2}+\frac{0.00098}{25+v^2}+\ldots\right]$$

At frequencies in excess of 20 kc, M_{21} is equal to $1/v$ and ΔR_t may be expressed as follows:

$$\Delta R_t=\frac{2.02\times10^{-3}f'}{v}$$

ohms per mile of pair where

$$v=\frac{0.05p'f't}{\rho} \qquad (32A)$$

f' = frequency, cps
p' = mean diameter of the equivalent sheath, inches
t = thickness of the equivalent sheath, inches
ρ = resistivity of the material in the equivalent sheath, microhm-inches

If the frequency is sufficiently high, above 50 kc in this case, the eddy currents will flow near the surface of the wires and the well-known "depth of penetration" formula may be used to calculate t.

$$\delta(\text{inches})=t=\left[\frac{10\rho}{\mu f'}\right]^{1/2}$$
$$=3.162\sqrt{\rho/f'} \text{ for copper}$$

If this value of t is used and if p', the mean diameter of the equivalent sheath, is taken as $4s$, then ΔR_t may be reduced to the following formula:

$$\Delta R_t=0.0884\,A_0xR_{dc}$$

where

$$x=2.845\sqrt{f/R_{dc}} \text{ given in equation 24} \qquad (32B)$$

Equation 32(B) correlates well with data taken in the frequency range of about 100 kc and higher. At lower frequencies, the thickness t must be determined by equating the resistance of the wires surrounding the pair to the resistance of a solid tube, which for the case of copper, and if 12 or more wires are considered to be in parallel and represent the sheath, the thickness is simply $t=0.35/p'R_{dc}$ inches. However, rather than calculate t at the lower frequencies, ΔR_t has been modified to the following:

$$\Delta R_t=\frac{xA_0R_{dc}}{10} \quad \text{for } x>5 \qquad (33)$$

$$\Delta R_t=\frac{xA_0R_{dc}}{16} \quad \text{for } 2.5<x<5.0$$

$$\Delta R_t=\frac{xA_0R_{dc}}{24} \quad \text{for } x<2.5$$

where x and R_{dc} are defined in equation 29 and A_0 is d/s, as defined in equation 30. In the computed values given in this paper, ΔR_t was considered to be zero for values of x less than 1. The experimental check made to establish the reliability of these formulas was accomplished by measuring the a-c resistance of a pair at 80 F when contained in the complete cable and then removing the pair from the cable and again measuring the a-c resistance. The resistance of the pair removed from the cable deducted from the original resistance is ΔR_t. The data obtained on the three cables, each containing 100 pairs, are given in Table XVII.

The use of equation 33 should be reliable for folded corrugated aluminum sheath similar in resistance to the cable studied. Since the eddy current loss in these sheaths

* Equation 33.

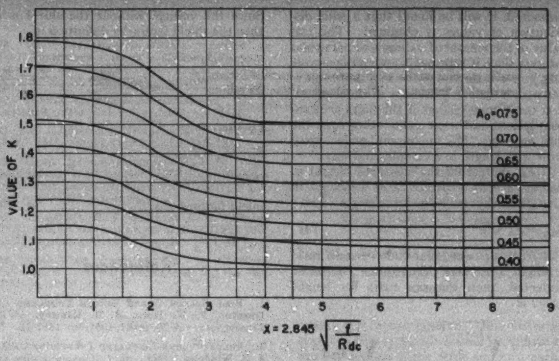

Fig. 25. Parameter K for equation 2(A) or 35 and 36

is so small, the equation should be reliable for cables with helically applied aluminum tapes which have a higher resistance. They have not been examined with cable having extruded aluminum sheaths; these latter cables may have different values of ΔR_t. Although this formula is based on cables having 100 pairs, it is expected to be reliable with a fair accuracy for any number of pairs, except perhaps for very small cables having fewer than 25 pairs.

Appendix IV. Inductance of a Pair Including Proximity Effect

The inductance of a single pair of wires in space including skin effect and proximity effect may be estimated from cable dimensions by the use of formulas developed by Carson[16] and Hebbert.[19] The following equation has been derived by Hebbert.

$$L=-4\log_e ks'+2KL_0 \qquad (34)$$

where

L = inductance of the pair per centimeter in centimeter-gram-second units

k = ratio $A_0/2$ (see equation 30)

$s'=\dfrac{1-\sqrt{1-4k^2}}{2k^2}$

K = correction factor of inductance L_0 for proximity effect and is a complex expression involving Bessel functions and is found from Fig. 25

L_0 = internal inductance of one wire with concentric return per centimeter in centimeter-gram-second units which includes skin effect only

L_0 has been defined by Hebbert[19] as follows:

$$L_0=\frac{2}{x}\,\frac{u_0u_0'+v_0v_0'}{u_1^2+v_1^2}$$

where x is given in equation 29, and u_0, u_0', v_0, v_0', u_1, and v_1 are the usual terms of the ber and bie functions related to the Bessel functions by the formula $u_n+iv_n=J_n(bi\cdot\sqrt{i})$ and $i=\sqrt{-1}$. Equation 34 may be rewritten as follows:

$$L=\left[1.485\log_{10}2s/d\times\frac{d^2}{2s(-\sqrt{s^2-d^2})}+0.161Kl(x)\right]\times 10^{-9} \qquad (35)$$

$$=\left[1.485\log_{10}\frac{d}{s-\sqrt{s^2-d^2}}+0.161\,Kl(x)\right]\times 10^{-3}\text{ henrys per loop mile of the pair} \qquad (36)$$

where

s = center to center spacing of the wires, inches

d = diameter of the wire, inches

$l(x)=2L_0$ and is obtained from Fig. 24

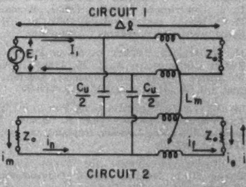

Fig. 26. Transverse crosstalk in a short element of paralleling pairs

Appendix V. Crosstalk Currents

By definition crosstalk is a ratio of power (P_2) induced in the disturbed circuit to the power (P_1) in the disturbing circuit. When expressed in db the crosstalk coupling loss is

$$10\log_{10}\frac{P_2}{P_1} \qquad (37)$$

When the characteristic impedances of both circuits are equal, the ratio of powers can be replaced by ratio of currents or voltages squared and the crosstalk loss becomes:

$$20\log_{10}\frac{E_2}{E_1}=20\log_{10}\frac{I_2}{I_1} \qquad (38)$$

Crosstalk can be expressed in crosstalk units, CU. Crosstalk unit is one millionth of one volt or ampere induced in the disturbed circuit by one volt or ampere, respectively, in the disturbing circuit. Crosstalk coupling loss in db, computed from CU, is

$$20\log_{10}\frac{E_2}{E_1}=20\log_{10}(\text{CU}\times 10^{-6})$$
$$=20\log_{10}\text{CU}-120 \qquad (39)$$

In 1907, Campbell[20,21] derived a convenient approximate expression for the crosstalk current or voltage ratio in an electrically short element of two long similar paralleling pairs of wires terminated in their characteristic impedance. This formula, while intended for use in studies of open wire, was soon adapted to cable studies. The derivation of the formula may be understood from Fig. 26.

The voltage E_1 drives a current $2i_e$ through the capacitance unbalance C_u and a current i_e appears at both ends of circuit 2. The current I_1 induces a voltage in circuit 2 by way of mutual inductance L_m and a crosstalk current i_m appears at both ends of circuit 2. The crosstalk currents i_e and i_m tend to add at the near end and to subtract at the far end of circuit 2.

The Campbell formula may be written:

$$\frac{I_2}{I_1}=\left[\frac{j\omega C_uZ_0}{8}\pm\frac{j\omega L_m}{2Z_0}\right] \qquad (40)$$

where

$\omega=2\pi f'$

f' = frequency, cps

C_u = capacitance unbalance in a short finite length Δl, farads

L_m = mutual inductance in a short finite length Δl, henrys

Z_0 = characteristic impedance of the line, ohms

The length Δl must be short enough to ignore phase change and long enough to involve approximately an integral number of times the least common multiple of the 2-pair twists. Then, with perfect twisting, the value of I_2/I_1 would be zero for any two pairs of unlike twist, of which one has an even number of twists in the length of common multiple.[22]

Much has been written[6,22] about the definition of C_u. Campbell's definition may

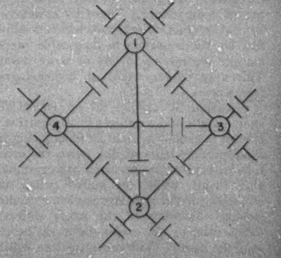

Fig. 27. Capacitance unbalance between two pairs

be understood by reference to Fig. 27 where *1–2* and 3–4 indicate two pairs: C_{13} indicates the direct capacitance between wires *1* and *3*, etc. Each of the wires *1* to *4* has many direct capacitances to other wires or to shield. C_u = capacitance unbalance $= C_{14} + C_{23} - C_{13} - C_{24}$.

This definition ignores certain second-order or "crosstalk of crosstalk" effects which, in well made cables, are unimportant, especially when no far-end balancing of crosstalk is employed.

In equation 40, each term contains $2\pi f'$ and tends to increase directly with frequency. However, the characteristic impedance Z_0 changes with frequency. The magnitude of Z_0 and of the angle θ both decrease with frequency as has been shown in Fig. 5.

For adjacent pairs C_u may have important values while for nonadjacent pairs C_u usually becomes negligible with the increase of number of separating pairs. At voice frequencies, the second, or I_m, term of equation 40 is usually neglected because of the high value of Z_0. This is particularly true if the pairs are loaded and have a higher impedance than Z_0.

At the carrier frequencies, Z_0 is relatively low. For adjacent pairs, the two terms of equation 40 become roughly equal and there is a marked tendency toward cancellation in the far-end crosstalk. For nonadjacent pairs, the second term becomes controlling and important. Nonadjacent pairs of like twist have been found to have serious far-end crosstalk at carrier frequencies and many different twist lengths are necessary to reduce mutual inductance.

For widely separated pairs of unlike twist, the simple Campbell formula may not apply. This covers "transverse" crosstalk, that is, the summation of crosstalk in a series of elemental lengths each Δl and neglects crosstalk between parts of primary and secondary circuits in different elemental lengths via tertiary circuits. This is known as "interaction" crosstalk[24] which may vary with length and frequency in a manner quite different from the simple transverse crosstalk within a section of cable between repeaters. This interaction crosstalk is not apt to be important since crosstalk currents arriving via transverse coupling are controlling except in cases where the transverse far-end crosstalk is substantially neutralized by crosstalk balancing units. This was done with the type K 12–60 kc carrier system. Crosstalk balancing has become obsolete because of new and cheaper methods of crosstalk reduction such as the use of compandors. There is, however, a type of interaction crosstalk which is amplified by the repeaters in long-cable carrier circuits repeated at one or more points. This may be important at higher carrier frequencies.

Equation 40 applies to an electrically short length and a process of summation is needed to establish crosstalk in long lengths. With parallel pairs of like twist, the crosstalk current ratio increases systematically with length while, for unlike twists, the crosstalk current ratio increases in a random fashion. In view of the many different twists used in the cables discussed herein, only the case of random summation will be discussed.

If, for a particular length, say 3,000 feet, a large number of values of current ratio are measured, it will be found that a wide distribution of values is obtained. The rms value of the measured values is of particular interest since it represents an average crosstalk power ratio and grows in a simple manner with length. The shape of the distribution curve may change if the pairs are random spliced and some value other than the rms, say the "1% maximum" value, may grow with length in a complicated way.

If F_Δ' represents the measured output to output far-end crosstalk ratio measured in a length Δ, the rms value for a length $n\Delta$ is

$$F_{n\Delta}' = F_\Delta'\sqrt{n} \tag{41}$$

If N_Δ' represents near-end crosstalk ratio in length Δ, so small that attenuation can be neglected, then the rms ratio for length $n\Delta = l$ is

$$N_l' = N_\Delta'\sqrt{\frac{1-e^{-4\alpha n\Delta}}{4\alpha\Delta}} = N_\Delta'\sqrt{\frac{1-e^{-4\alpha l}}{4\alpha\Delta}} \tag{42}$$

where α is attenuation in nepers per unit length and N_Δ' refers to the crosstalk ratio excluding the attenuation of crosstalk currents on their way to the near end. To include that attenuation, for instance when crosstalk current ratio N_{nl}' is computed from near-end crosstalk ratio N'_l measured on a length of cable l miles long, equation 42 is changed to:

$$N_{nl}' = N_\Delta'\sqrt{\frac{1-e^{-4\alpha nl}}{4\alpha\Delta}} = N_l'\frac{\sqrt{\dfrac{1-e^{-4\alpha nl}}{4\alpha\Delta}}}{\sqrt{\dfrac{1-e^{-4\alpha l}}{4\alpha\Delta}}}$$

$$= N_l'\sqrt{\frac{1-e^{-4\alpha nl}}{1-e^{-4\alpha l}}} \tag{43}$$

The near-end ratio grows more slowly than $\sqrt{n}$ because of the effect of attenuation. If n is very large, the numerator under the radical approaches unity.

Appendix VI. Shield Factor

The shield factor is an expression of the ratio of induced voltage in a shielded cable to that of the same cable unshielded. In the case of magnetic induction, where the shield and shielded conductors are closely associated in space, the external voltages induced longitudinally along the shield and along the shielded conductors are substantially equal. This voltage (E) is called the primary field. Assuming zero ground impedance, current i_s in the shield is equal to E/Z_{11} where Z_{11} is the ground return self-impedance of the shield. This current induces, along the shielded conductors, a counter voltage (E') called the secondary field which is equal to $i_s Z_{12}$ where Z_{12} is the ground return mutual impedance between the shield and the shielded conductors. The resultant voltage along the shielded conductors is then:

$$E - E' = E - i_s Z_{12} = E - \frac{E}{Z_{11}} Z_{12}$$

$$= E\left(1 - \frac{Z_{12}}{Z_{11}}\right)$$

$$= E\frac{(Z_{11} - Z_{12})}{Z_{11}} \tag{44}$$

Since the voltage without the shield is E, then the shield factor by definition is

$$S_f = \frac{E\dfrac{(Z_{11}-Z_{12})}{Z_{11}}}{E} = \frac{Z_{11}-Z_{12}}{Z_{11}} \tag{45}$$

Further, since

$Z_{11} - Z_{12} = Z_{ab}$

then

$$\text{shield factor} = Z_{ab}/Z_{11} \tag{46}$$

◆

Discussion

J. V. Buscemi (Rural Electrification Administration, U. S. Department of Agriculture, Washington, D. C.): Crosstalk characteristics have been presented in this paper in sufficient detail regarding frequency and position of pairs in the cable that the telephone system application engineer has an adequate guide as to which of the pair combinations may contribute controlling crosstalk. Under certain conditions, at repeater points, however, not transverse but interaction crosstalk may be controlling. This may occur when the repeater gain desired is higher than the conditions of interaction crosstalk allow.

It would be of value if the authors could supply data on the magnitude of repeater gain at which interaction crosstalk becomes equal to or more pronounced than the far- and near-end transverse crosstalk indicated in the paper.

G. S. Eager, Jr., L. Jachimowicz, I. Kolodny, and D. E. Robinson: We feel that Mr. Buscemi's point is very well taken since interaction crosstalk (coupling loss) may determine the permissible repeater spacing and gain. In answer to this question, the following comments and data are furnished.

In effect, near-end, near-end interaction crosstalk is near-end crosstalk repeated twice and amplified at the repeater point. The signal amplified at the repeater point and sent in one direction, for instance, east, appears as a near-end crosstalk in a pair or pairs of the local circuits which are continuous at the repeater point. The disturbing signal of this crosstalk travels back into the western section of the cable and by a path of near-end crosstalk appears on the western termination of the carrier pair in which the signal arriving for amplification is weak. Interaction crosstalk will not achieve the controlling magnitude of its crosstalk coupling loss expressed in db minus the value of repeater gain in db but will be equal or larger than controlling transverse far-end crosstalk coupling loss of the repeater section.

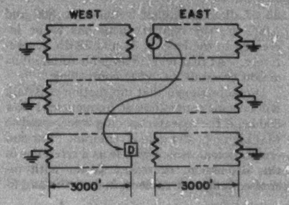

Fig. 28. Schematic diagram of circuit used in measuring near-end, near-end interaction crosstalk

The interaction crosstalk coupling loss given in Table XVIII was measured on the same two 100-pair 0.083 μf per mile 19 Awg cables, each 3,000 feet long, used for the other crosstalk measurements described in this paper. The cables were spliced straight color to color, as shown schematically in Fig. 28. Pairs not under direct test were terminated at both ends of the 6,000-foot length in resistors, center taps of which were grounded, so as to simulate a long line and suppress reflection from termination of phantoms and other tertiary circuits. The disturbed and the disturbing pairs were cut in the middle of the 6,000 foot length, and terminated into precision networks. The disturbing signal was fed into the eastern 3,000-foot section and the signal received in the disturbed pair was measured, arriving at the 3,000-foot mark of the western section of the cable. The ends of inactive halves of the disturbed and disturbing pairs at the middle of the cable were terminated in resistors, the center taps of which were not grounded.

It can be noted that the test was conducted, on purpose, in most unfavorable conditions with all pairs, except for two under test, uninterrupted at the repeater point. No clear pattern of increase in crosstalk coupling loss, with increase of separation between pairs, has been observed. A disturbing pair induces crosstalk in a multitude of tertiary circuits in the eastern portion of the cable which, in turn, induces voltages in pairs of the western portion of the cable, without much difference whether pairs are closely associated in space in the eastern or in the western section of the cable.

Table XIX. Measured Rms Crosstalk Losses in Db Corrected to 10,000-Foot Adjacent Pairs

Frequency, Kc	Interaction Crosstalk Coupling Loss: Before Amplification	Interaction Crosstalk Coupling Loss: Equal Level after Amplification	Far-End Equal Level Crosstalk Loss	Difference

loss will decrease much less with the increased length of cable, the decrement being twice the small decrement of near-end crosstalk loss. As shown in Fig. 20, the value of near-end crosstalk loss changes little from the value measured on a 3,000-foot length at frequencies above 100 kc.

It can be seen from Table XIX that in 10,000 feet of 19 Awg 0.083 cable near end, near-end interaction crosstalk is not controlling as long as line attenuation losses and, therefore, repeater gains do not exceed some 25–27 db. At higher frequencies, 800 and 1,000 kc, the repeater gain has to be increased to the level of 33 and 38 db, respectively. At that level of amplification, interaction crosstalk becomes controlling.

It can be shown that interaction crosstalk will become controlling at frequencies below 800 kc, if the repeater spacing is increased so that high repeater gain is required. Far-end crosstalk loss, which we use as a reference in this discussion, decreases slower with increased length of cable than does the amplified interaction crosstalk loss. When the length of cable is increased n times, the far-end crosstalk loss, expressed in db, will be $F_n = F_0 - 10 \log_{10} n$ and amplified interaction crosstalk $N_{tn} = N_{t0} - \alpha n$ where N_{t0} is practically constant for longer lengths of cable and α is line attenuation of the $1/n$ length of cable. As n is increased, there will always be a point at which $N_{tn} < F_n$, that is, repeater spacing at which near-end, near-end interaction crosstalk will become controlling.

An Electric Analog of Heat Flow in Power Transistors

Synopsis: An electric analog of heat flow in alloyed-junction power transistors was constructed to facilitate a study of instantaneous crystal temperatures under various pulsed conditions. An equivalent T-section transmission line using lumped constants was chosen as a suitable analog. The derivation of the transmission-line analog is given, along with construction and operating procedures. A short comparison of analog and experimental data is included.

IN THE DESIGN of circuits utilizing power transistors, the maximum allowable instantaneous junction temperature is often the major limitation on the power carrying capabilities of the circuit. Transistor failure may result if the junction temperature exceeds, even momentarily, a certain maximum value.

While the maximum safe-operating junction temperature is usually given by the manufacturer, it is often difficult to determine what the junction temperature actually is under various excitation conditions. An electric analog of heat flow in power transistors can be designed to give, immediately, the temperatures throughout the crystal under a wide variety of excitation conditions. Further, the analog may be used to study ways of extending the maximum safe-operating temperature.

Fourier's heat-flow equation in one-dimension is analogous to the equation for voltage variation along a transmission line. By reducing the heat-flow model of a power transistor to a one-dimensional model, one may simulate the transistor with a transmission line. To simplify construction and operation, the continuous transmission line may also be simulated with an equivalent T-section lumped-parameter line.

Derivation of Analog

A complete analysis of the heat flow in an alloyed-junction power transistor would be extremely complex. Several simplifying assumptions are possible, however, which do not greatly affect the accuracy of the results.

The first of these assumptions, that radiation losses are negligible, can be validated by use of

$$q = A\sigma E(T^4 - T_0^4) \qquad (1)$$

where

q = total heat loss due to radiation, erg/sec (second)
σ = Stefan-Boltzmann constant, 5.672 (10^{-5}) erg/sec centimeter^2 degrees Kelvin^4
E = emissivity of radiator crystal
T_0 = temperature of receiver (case), degrees Kelvin
T = temperature of radiator, degrees Kelvin
A = total area of radiator, centimeter^2

The crystal is assumed to be a perfect radiator with an emissivity of one. The temperature difference between the crystal and the case is assumed to be sufficient to damage the crystal (approximately 80 C (degree centigrade) for most power transistors). Solving equation 1 for q with these assumptions gives the maximum possible heat loss caused by radiation.

The maximum heat loss due to radiation for the Minneapolis-Honeywell type *H-6* transistor is approximately 0.082 watt for a total average power input of approximately 40 watts. This 40 watts of input power is sufficient to damage the transistor regardless of the heat sink used. Maximum radiation losses, then, will amount to only 0.205% of the total power dissipated for the *H-6* transistor.

Since heat loss due to natural convection is approximately proportional to the 5/4 power of the temperature difference,[1] it will certainly be less than the loss due to radiation. Doubling the radiation loss, then, will give a value for radiation and natural convection losses which will be higher than is actually the case. Thus the total heat losses due to radiation and natural convection are less than 0.41% of the total power dissipated for the *H-6* transistor.

The heat loss caused by conduction through the gas surrounding the crystal is easily shown to be very small by use of

$$q = \frac{KA\Delta T}{d} \qquad (2)$$

where

q = heat loss, calorie/second
K = heat conductivity of the gas, calorie/second-C-centimeter
A = total area of the crystal, centimeter^2
ΔT = temperature difference between crystal and case, C
d = distance from crystal to case, cm (take d a minimum to obtain q maximum)

The heat conducted away through the gas in the *H-6* transistor is approximately 0.02 watts maximum for a total average power input of 40 watts.

Maximum heat loss due to radiation, natural convection, and conduction through the gas, then, will be less than 1/2 of 1% of the total power dissipated for the *H-6* transistor. These losses should not

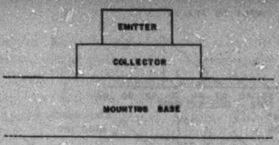

Fig. 1. The thermal model

be over 1% of the total power dissipated for any gas-filled power transistor.

By neglecting these heat losses, the heat flow problem is greatly simplified. If it is assumed that all elements of the crystal are homogeneous and cylindrical in shape the one-dimensional thermal model shown in Fig. 1 may be used.

Fourier's equation of the heat flow in this one-dimensional model may be expressed as

$$\frac{\partial T}{\partial t}=\alpha_T\frac{\partial^2 T}{\partial x^2} \tag{3}$$

where

T = temperature
X = distance from junction
α_1 = thermal constant of crystal
t = time

Equation 3 is the standard equation for voltage variation along a transmission line

$$\frac{\partial V}{\partial t}=\alpha_e\frac{\partial^2 V}{\partial x^2} \tag{4}$$

with voltage replaced by temperature and the electricl constant α_e replaced by the thermal constant α_T.

A transmission line, then, is one analog for the one-dimensional heat flow problem. An equivalent T-section transmission line using lumped constants was chosen as the easiest to construct and operate.

Table I. Useful Analogies in Selection of Component Sizes and Number of Sections in Constructing the Analog

	Electrical	Thermal
Conservation of Scalar quantity	charge, coulombs	heat, calories
Scalar point function	electric potential, volts	temperature, degrees
	Ohm's law	Fourier's law
Resistance concept	$R_e=dV/I$	$R_t=dT/q$
	R_e = electric resistance	R_t = thermal resistance
	I = current through R_e	q = heat flow through R_t
	dV = difference in potential across R_e	dT = difference in temperature across R_t
Capacity concept	$C_e=Q_e/dV$	$C_t=Q_t/dT$
	C_e = electric capacity	C_t = thermal capacity
	Q_e = charge stored in C_e	Q_t = heat stored in C_t
	dV = rise in electric potential of C_e because of Q_e	dT = rise in temperature of C_t due to Q_t
One-dimensional form of heat conduction equation for solids	t_e = time in electric circuit	t_t = time in thermal circuit
	x_e = distance along cable	x_t = distance along flow path
	V = electric potential at X_e at time t_e	T = temperature at x_t at time t_t

Capacity	farads, coulombs/volt	calorie/C
Resistance	ohms, volts/coulomb/second	C/calorie/second

Construction of Analog

The question of component size and the number of sections required to construct our analog immediately arises. The analogies given in Table I are useful in answering these questions.

Using the procedure outlined in Creamer,[2] it was determined that 50 identical T sections for both the emitter and collector and 10 T sections for the base region would simulate the transmission line up to a frequency of 50 kc. This frequency range was extended somewhat by tapering the line. In constructing the analog, considerable choice is allowed in the selection of component sizes if the proper scaling technique is employed. The following scaling constants may be employed:

L = scaling constant for voltage and temperature
N = scaling constant for time
$1/M$ = scaling factor for capacitance
NM = scaling constant for resistance
L/NM = scaling factor for current and heat flow

Since the analog must be fed by a current source, (with no input to analog, the source must not provide a discharge path) the factor NM is of primary importance in the design of the feed source. The output impedance of the feed source must be several (10 or more) times the impedance of the analog. Taking the output impedance (preferably a pure resistance) of an easily realizable current generator, we fix the value of NM with inequality

$$R_e(NM)\leq\frac{Z_0}{10}$$

using this value of NM, we calculate R_e with the equation

$$R_e=\frac{R_t}{NM}$$

where R_t is the total thermal resistance of either the collector or emitter.

R_t is given by

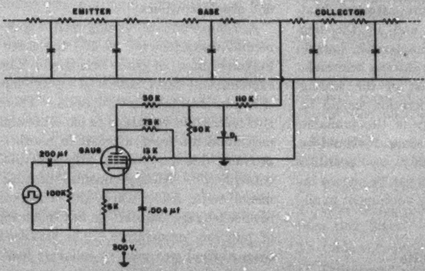

Fig. 2. Power transistor heat flow analogy and current generator

Collector = 50 T sections
Emitter = 50 T sections
Base = 10 T sections

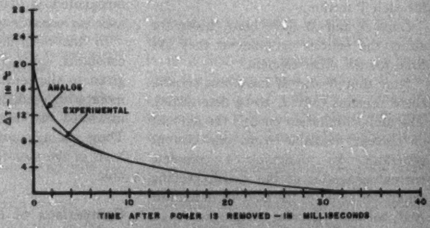

Fig. 3. Measurements of versus "off" time

Pulse width = 10 milliseconds
Period = 50 milliseconds
Peak power = 42 watts

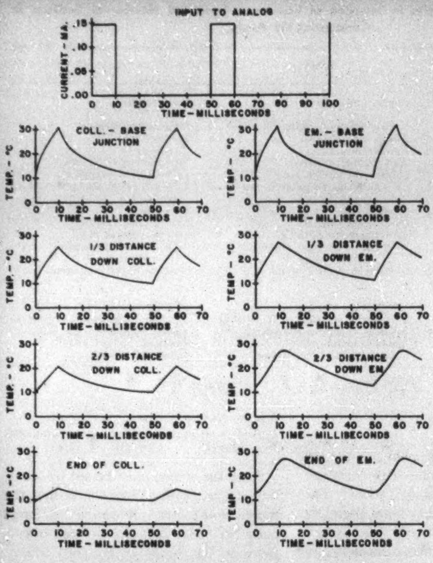

Fig. 4. Analog waveforms for rectangular pulsed input

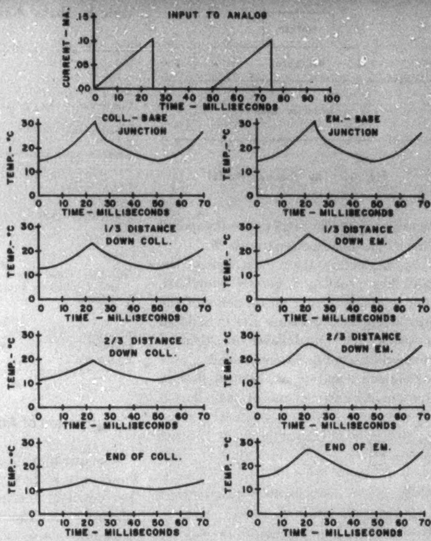

Fig. 5. Analog waveforms for sawtooth input

$$R_t=\frac{d}{KA}$$

where

d = depth
A = area
K = heat conductivity

This value of R_t is divided by twice the number of T section to obtain the resistance for each arm of each T section.

Since $C_e=MC_t$, one is free to choose a value of m which will give a convenient value for the electric capacity, when the factor NM is kept constant. The value so chosen is divided by the number of T sections to obtain the value of capacity for each T section.

Once N and M have been chosen for either the emitter or collector they are fixed for the other element.

Now that N and M have been chosen, there remains only L to be determined. The major limitation on L is the amount of current available from our current generator. By designing a complete current generator at this point, keeping mind the value of Z_0 used to determine NM, solve for L using

$$L=\frac{NM}{I_{\max}}q_{\max}$$

where $I_{\max}$ is the maximum current available from our current generator and $q_{\max}$ is the maximum heat flow of interest. LV now corresponds to the heat flow into the crystal necessary to produce this temperature. Thus a variation in the current from the generator corresponds to a variation in heat flow into the crystal and a variation of voltage along the line corresponds to a variation of temperature through the crystal.

The scaling constants used to determine the electrical constants of the T sections for the base, collector, and emitter are also used to determine the electrical constants needed to simulate the copper mounting base and any attached heat sinks. The collector end of the line terminated in its characteristic impedance corresponds to an infinite heat sink.

In the determination of the scaling constants, some consideration should be given to the sensitivity of the available monitoring equipment since V should be measured as accurately as possible. These scaling constants can be chosen on basis of the monitoring equipment available.

Comparison of Results

Rather than compare exact experimental and analog temperatures, it is simpler to compare values of ΔT. ΔT is defined as the difference between maximum junction temperature (the temperature at the end of the power pulse) and minimum junction temperature (the temperature at the beginning of the power pulse). Using ΔT for comparison purposes allows the clamping diode, D_1 in Fig. 2, to clamp the input pulse to a zero reference level. This clamping removes the ambient temperature factor from the analog, thus simplifying the analog operating procedure. Further, we are able to utilize the maximum sensitivity of our monitorying equipment, since we are interested only in voltage differences and not absolute values.

A comparison of analog and experimental measurements of ΔT, for a rectangular pulse, is given in Fig. 3. The experimental curve shown is an average of measurements for several units. There is considerable variation in experimental measurements from one unit to another, probably due to nonuniformity of crystal construction. All experimental measurements were made using the collector reverse-leakage current as the indicator of junction temperature. The standard oven method was used to calibrate leakage current versus junction temperature.

As shown in Fig. 3, there is good agreement in measurements of over most of the cooling cycle. However, no reliable experimental data are available for the period immediately following the removal of the power pulse. Considerable difficulty has been encountered in attempting to separate, experimentally, the electrical and thermal effects during this period. It is expected that, once experimental data is available, analog and experimental measurements will essentially agree throughout the cooling cycle.

The difficulty in obtaining experimental data immediately following the power pulse is eliminated with the analog. Measurements of temperature throughout the cycle, both heating and cooling portions, are readily available using the analog.

The complete power cycle, as given by the *H-6* analog for two different waveforms, is shown in Figs. 4 and 5. The variations in temperature, with time, are shown for various points in the crystal. Note that the emitter and collector junctions are at essentially the same temperature throughout the cycle. This indicates that if a transistor were operating near the thermal failure temperature, any increase in power applied to the emitter junction might cause the emitter junction to fail since its temperature could be higher than that of the collector.

Several transistors were damaged under collector pulsed conditions. The power was removed before thermal runaway was completed. These transistors showed damage to the emitter junction only. Usual failures under thermal runaway conditions result in damage to both junctions.

Thermal runaway conditions may by simulated with the analog by adding a second current generator to the input. The second current generator would correspond to the power input to the crystal caused by leakage current.

Some of the other advantages of the analog as compared to experimentally obtained data are:

1. Measurements of temperatures anywhere in the crystal are possible with the analog. The only temperatures immediately available experimentally are the temperature at the junction and the temperature of the mounting base.
2. Changes in the physical geometry (size of base fin, collector termination, size of emitter and collector, etc.) are easily made on the analog.
3. Ambient temperature effects may be noted on the analog without ovens or refrigeration.
4. Changes in transistor characteristics with age and environment which necessitate constant calibration for experimental data are eliminated in the analog.
5. Measurements of power input necessary to raise junction temperature to a dangerous level under various pulsed conditions can be made, with the analog, with no risk of damaging transistors.
6. With the analog, the time required to obtain specific pulse data is greatly reduced.
7. The effect of various cooling techniques may be investigated, quite easily, with the analog.
8. In using the analog, a mathematical representation of the waveform under study is not necessary. If the waveform can be generated and applied to the analog the temperature may be determined at any point in the crystal.

Transistor-Magnetic Control Circuits for Aircraft Electric Systems

A. W. PRATT
ASSOCIATE MEMBER AIEE

THE STRINGENT requirements for military aircraft electric systems necessitates the optimum utilization of the latest component developments. The circuitry described in this paper is intended to combine semiconductor diodes and transistors with square-loop magnetic cores in a manner that results in the maximum use of their desirable characteristics. The memory capability of square-loop magnetic cores and the switching characteristics of transistors are employed in a complementary manner. As a result, the following advantages are obtained:

1. The transistor-magnetic high-phase and low-phase sensing circuit inherently senses the "true average" value of the system alternating voltages. In other words, it senses the total amount of volt-seconds underneath the positive half cycles of the voltages. This is in contrast to conventional circuits which sense either the peak value or only a small fraction of the volt-seconds underneath the waveform.
2. Because only the switching characteristics of the transistors are utilized, circuit operation is practically independent of variations in transistor characteristics.
3. The circuits use only small, static, reliable, and rugged components. Capacitors, which are used in conventional circuits, are replaced in this circuit by square-loop magnetic cores which are less temperature sensitive and much more reliable.

The transistor-magnetic circuits that are introduced in this paper are

1. High- and low-phase sensing circuit.
2. Overvoltage protection circuit with inverse time delay.
3. Undervoltage protection circuit.
4. Unbalanced phase protection circuit.
5. Fixed time-delay circuit.

The block diagram of Fig. 1 shows one possible combination of these circuits to provide protection for a 3-phase system. The pulse delay reactor shown simply delays any output pulse from the undervoltage circuit that may occur so that it will not be applied to the fixed time-delay circuit when this circuit is being reset and is consequently unable to respond. The circuitry for accomplishing this function will not be discussed in detail since it may assume a number of conventional forms. The latching circuit shown may also be conventional and so it will not be described.

High- and Low-Phase Sensing Circuit

In order to provide maximum protection in a multiple-phase electric system it is desirable to monitor the highest and the lowest phase voltages of the system. It is not sufficient to monitor the average value of the phase voltages by means of a 3-phase bridge rectifier for

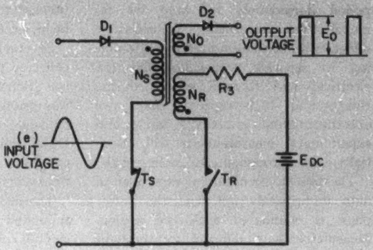

Fig. 2 (right). Simplified, single-phase pulse-forming circuit

a 3-phase system for example. Fault conditions are possible which will cause one phase voltage to be considerably higher than the others, while causing the average value of the phase voltages to be less than the specified maximum value It is obvious that this condition may produce harmful effects on the system load if the overvoltage protection circuit senses the average value of the 3-phase voltages. However, if the circuit sensed only the highest of the phase voltages, it is apparent that none of the phase voltages would exceed the specified maximum value. Consequently, every portion of the load would be protected against overvoltage.

A parallel example could be cited for an undervoltage condition demonstrating the desirability of having low-phase sensing for the undervoltage protection circuit.

Another requirement in some a-c systems is that the average value of each phase voltage be monitored rather than the peak value. One reason for this preference is that the average value of the voltage indicates more accurately the heating effect of the voltage upon load devices.

The high- and low-phase sensing circuit that will be described senses the true average values of the highest and the lowest phase voltages of a 3-phase system. By "true average" sensing of an alternating voltage is meant that the circuit can sense essentially all of the volt-seconds underneath the waveform of the voltage. This is in contrast to the sensing of only a small portion of the volt-seconds underneath the waveform that is performed by some circuits that are termed average sensing

SINGLE-PHASE PULSE-FORMING CIRCUIT

The circuit of Fig. 2 is capable of producing a rectangular voltage pulse at its output terminals which contains an amount of volt-seconds that is proportional to the volt-seconds underneath the positive portion of the input voltage waveform. In order to do this, it is necessary that the switches T_s and T_R, which are intended to simulate transistors, be operated in a specified manner.

For purposes of explanation, assume that the input voltage is approximately a sine wave. During the sensing period switch T_s is closed and T_R is open. Because of diode D_1 only the positive portion of the input voltage is applied to winding N_s. Therefore the flux change produced on the core is proportional to the amount of volt-seconds underneath the positive half-cycle of the input voltage. During this time diode D_2 blocks current flow in winding N_o and the open switch prevents current flow in winding N_R. Consequently, there is no induced current flowing in the input circuit during the sensing period. The resistive voltage drop in this circuit is therefore caused mainly by the magnetizing current required by N_s and is negligible.

Sometime during the negative half-cycle of the input voltage, switch T_s is opened and T_R is closed. The voltage E_{dc} is then applied to winding N_R until the core saturates in the negative direction. It should be noted at this point that resistor R_3 is small so that the voltage drop produced across it by the magnetizing current required by N_R prior to saturation is negligible in relation to E_{dc}. Prior to saturation of the core a voltage is induced in winding N_0, with the polarity shown, that is proportional to E_{dc}. Since the change in flux during this reset period must be equal to the change in flux that occurred during the previous sensing period, the voltage pulse that occurs at the output terminals contains an amount of volt-seconds that is proportional to the volt-seconds underneath the positive half cycle of the input voltage. It should be noted that the open switch T_s prevents current flow in winding N_s during this reset period.

THREE-PHASE PULSE-FORMING CIRCUIT

In order to produce the required pulse for each of the three phases the circuit shown in Fig. 3 is used. It is noted that the input winding of the transformer for phase B is inverted with respect to the similar windings of phases A and C. It will be shown later why this is necessary.

The circuit operates in the following manner. As described for the single-phase circuit, each of the three pulse-

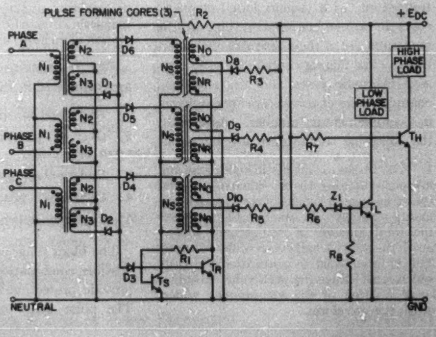

Fig. 3. High-phase and low-phase sensing circuit

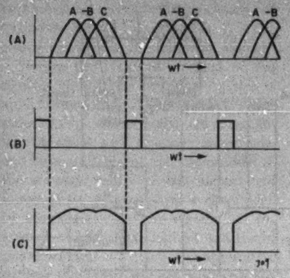

Fig. 4. Waveform sketches showing switching sequence of transistors in high- and low-phase sensing circuit

A—Rectified input voltages
B—Base voltage on reset transistor
C—Base voltage on sensing transistor

forming cores has a flux change during the sensing period that is proportional to the volt-seconds underneath the positive half-cycle of its phase voltage. This statement is made in reference to the secondary voltages of the three input transformers. The phase relationship of these voltages is shown in Fig. 4. Because the voltage of phase *B* is inverted, as described previously, the phase difference between the three voltages is 60 degrees. Transistor T_s remains closed until each of the three positive half-cycle voltages is "read" by its respective pulse-forming core.

The three cores are reset in parallel during the 60-degree period when all of the input transformer secondary voltages are negative as shown in Fig. 4.

During this "readout" period each of the three output windings produces a pulse that has a volt second content that is proportional to the volt-second content of its phase voltage. It is shown in Appendix I that this pulse is also proportional to the "true average" value of the phase voltage and inversely proportional to the system frequency.

Method of Sensing High- and Low-Phase Pulses

The high-phase output signal is obtained by applying the sum of the three output voltages to the base of the high-phase transistor in such a manner that any one of the output voltages by itself is sufficient to saturate that transistor. This is accomplished by connecting the output windings of the three cores in series so that their voltages add and setting the value of the base resistor R_7 so that the high-phase transistor is saturated when any one of the output voltages is present. It is also necessary that the current flowing in the output windings be less than the magnetizing current required by these windings so there is no positive change in flux of the cores during the reset period.

As a result of the foregoing considerations, the length of time that the high-phase transistor is on is seen to be equal to the width of the high-phase pulse. If the high-phase load is placed in series with the collector of this transistor, and the voltage E_{dc}, which is the same as that voltage which was used to reset the cores, is applied to this load, the volt-seconds of the pulse which occurs across the load during the reset period is proportional to the average value of the high-phase input voltage and inversely to the system frequency.

In order to sense the low-phase pulse, the sum of the three output voltages is applied through a Zener diode Z_1 to the base of the low-phase transistor. The breakdown voltage of Z_1 is such that the base feed of the low-phase transistor is insufficient to allow it to conduct when any one of the three output voltages disappears. If the load for this transistor is placed in series with its collector and the voltage source E_{dc} as for the high-phase transistor, the volt-second content of the voltage pulse produced across the low-phase load will be proportional to the average value of the low-phase system voltage and inversely proportional to the system frequency.

Method of Producing Proper Switching of Transistors

As described in the foregoing it is required that transistor T_R conduct during the 60-degree period when the voltages of phases *A* and *C* are negative. The "and" circuit, which consists of diodes D_1, D_2, D_3 and resistor R_3, applies a voltage to the base of T_R only for this condition. This voltage biases transistor T_R to saturation during the proper period.

Resistor R_1 causes the sensing transistor T_s to be biased to saturation when transistor T_R is off, and causes it to be biased off when transistor T_R is biased to saturation. Thus, it is seen that the circuit of Fig. 3 provides for proper switching of the transistors.

Overvoltage Circuit with Inverse Time Delay

In this circuit the high-phase pulse that was described as the high-phase output pulse for the high- and low-phase sensing circuit is compared to a reference pulse whose width is equal to one half of the period of the sensed voltage and whose magnitude is regulated at a constant voltage. When the average value of the highest phase voltage exceeds a specified value, an output signal is produced after a time delay which is inversely proportional to the difference between the average value of the highest phase voltage and the magnitude of the voltage of the reference pulse. A detailed analysis of the operation of this circuit is given in Appendix II. A general description of operation is given in the following.

The circuit is shown in Fig. 5. The

winding N_s constitutes part of the high-phase load that was described for the high- and low-phase sensing circuit. Therefore, the pulse that is applied to this winding during the "readout" period for the sensing circuit has a volt-second content that is proportional to the volt-second content of the system high-phase voltage. The flux change produced on the overvoltage core during this period is proportional to the average value of the highest phase voltage and inversely proportional to the system frequency.

During the next "read" period for the sensing circuit, the overvoltage core is reset by a reference pulse. To do this, the reset transistor T_R is biased to saturation by the secondary voltage of phase B. This voltage controls this transistor so that it is biased to saturation for essentially the total time of one half the period of this voltage. As a result of these considerations, it is seen that the flux change produced on the overvoltage core when it is reset is proportional to the constant voltage E_c and is inversely proportional to the frequency of the system voltages. Because both the input pulse to this circuit and the reset pulse are inversely proportional to the frequency, the comparing function that is performed on the overvoltage core is independent of frequency.

When the average value of the highest phase voltage is such that the net flux change is zero after an input pulse has been applied to the overvotage core and the core has been reset, the minimum trip condition is present. When the average value of this voltage is less than the minimum trip value, the overvoltage core saturates during its reset period. When this occurs, the current through N_R is limited by the base feed of transistor T_R. When the average value of the highest phase voltage exceeds the minimum trip voltage, the overvoltage core saturates after a time delay during a "readout" period of the sensing circuit and the high current pulses that occur as a result produce high narrow voltage pulses at the output terminals across R_2.

If the highest phase voltage is instantaneously increased from a normal value to one that is greater than the minimum trip voltage, the overvoltage core will saturate after a time delay which is inversely proportional to the difference between the average value of the alternating voltage and the minimum trip voltage (equation 19 in Appendix II). For each complete cycle of the alternating voltage there is a small net flux change in the overvoltage core. This flux change is inversely proportional to the frequency and since the number of pulses applied to the core is proportional to the frequency, the time required for the operating point of the core to reach saturation is approximately independent of frequency.

The reference voltage E_c, which is required to form the reset pulse, is provided by the Zener diode Z_1 and resistor R_1. The potentiometer P_1 and the resistor R_4 are provided for adjustment of the minimum trip voltage.

Undervoltage Protection Circuit

The function of an undervoltage circuit is to produce an alarm signal when the average value of the lowest phase voltage is less than a specified value. The circuit of Fig. 6 performs this function essentially independently of the system frequency. The circuit operates in the following manner.

During the "readout" period of the high- and low-phase sensing circuit, the low-phase pulse is applied to winding N_s of the undervoltage core. As described previously, this pulse is constant in magnitude and its width is proportional to the average value of the lowest phase voltage divided by the frequency of the system. This voltage pulse produces a proportional positive flux change on the undervoltage core. Transistor T_R is open during this period so induced current does not flow in winding N_R.

Reset of the undervoltage core occurs during the "read" period of the high- and low-phase sensing circuit. Transistor T_R is then biased to saturation for a period of time inversely proportional to the system frequency. As for the overvoltage circuit, this frequency dependence is introduced to compensate for the frequency dependence of the low-phase pulse, so, in effect, the comparing function performed on the undervoltage core is essentially independent of the system frequency. The voltage pulse applied to winding N_R during this period has a constant magnitude E_c resulting from the regulating action of Zener diode Z_1. This pulse produces a proportional negative flux change on the undervoltage core.

The turns-ratio of the undervoltage core and the value of E_s is chosen so there is no net flux change per cycle when the average value of the lowest phase voltage is equal to the specified minimum voltage. When it is higher than this value, the core will saturate in the positive direction. When this occurs the current through winding N_s is limited by the base signal on the low-phase transistor T_L of Fig. 3. When the average value of the lowest phase voltage is less than the minimum specified value, the core will saturate after a number of cycles in the negative direction during the reset period for the undervoltage circuit. An alarm signal then occurs in the form of narrow voltage pulses across resistor R_2.

Unbalanced Phase Protection Circuit

The function of an unbalanced phase protection circuit is to provide an alarm signal when the difference between the average values of the highest phase voltage of the system and the lowest is greater than a specified value. This function is performed essentially independently of frequency by the circuit of Fig. 7. The circuit operates in the following manner.

During the "readout" period of the sensing circuit the high-phase pulse is applied to winding N_H and the low phase pulse to N_L. These pulses are rectangular, of equal and constant magnitude, and have widths that are proportional to the average values of the highest and lowest phase voltages respectively divided by the frequency of the system. If the average values of the highest and lowest phase voltages are equal, the application of these two pulses will not produce a flux change on the unbalanced phase core because winding N_H and N_L are wound in opposite directions. However, if the highest phase voltage is greater than the lowest, there will be a positive change in flux that is proportional to the difference. During this period transistor T_R blocks the flow of induced current in the reset winding N_R.

During the "read" period of the high- and low-phase sensing circuit, transistor T_R is biased to saturation for a period of time inversely proportional to the system frequency. Consequently, a voltage pulse whose magnitude is E_c (a constant value determined by the combination of zener diode Z_1 and resistor R_1) is applied to winding N_R. This pulse causes a negative flux change on the unbalanced phase core of an amount that is inversely proportional to the system frequency. This frequency dependence compensates for the frequency dependence of the high- and low-phase pulses so the flux change per cycle is essentially independent of the system frequency.

It is therefore apparent that the core will remain at negative saturation so long as the difference between the average values of the highest and lowest phase voltages is proportionally less than the voltage E_c. When this difference is greater than this value, the core will become saturated in the positive direction after a number of cycles, and an alarm signal will appear in the form of narrow voltage pulses across the resistor R_3.

Fixed-Time Delay Circuit

This circuit is shown in Fig. 8. It is intended to provide an output signal a specified period of time after the application of an input signal. It will be shown in the following that the circuit is essentially independent of frequency variations over a normal aircraft frequency range and that it has a practically "instantaneous reset" characteristic.

Circuit operation is as follows. Assume initially that core A and core B have been reset to positive saturation. When an input signal is present, narrow negative voltage pulses are applied to transistor T_s. Because of the feedback produced by winding N_f, each of these pulses causes the voltage E_c to be applied to winding N_s until core A saturates in the negative direction. It should be noted that this action is independent of the shape of the input pulse. During the time that the operating point of core A is moving from positive saturation to negative saturation, a voltage

$$\frac{N_0}{N_s} E_c$$

is applied to winding N_T of core B. Consequently, there will be a small flux change on core B proportional to the maximum flux density of core A.

After core A has saturated in the negative direction, the voltage induced in winding N_f disappears and transistor T_s is biased off. Transistor T_R is then biased on for a period of time equal to one half the period of a system alternating voltage. This is accomplished by clipping a half sine wave of the alternating voltage with a Zener diode and applying this voltage to the base of T_R. Zener diode Z_1 and resistor R_2 provide this voltage pulse. There is a resulting flux change on core A during this reset period that is proportional to the constant voltage E_c and inversely proportional to the frequency. At this time a design requirement will be noted. Reactors A and B will be designed so that the magnetizing current required by N_R' will be much greater than that required by N_R. Because of this requirement all of the reset volt-seconds is absorbed by winding N_R during the reset period unless core A saturates. The core does not saturate unless the input signal is removed, and so for the present analysis, we will assume that all of the reset volt-seconds are absorbed by winding N_R. The induced current in winding N_0 is blocked during the reset period by diode $D2$ and, therfore, the flux change on core B is zero during the reset period.

The next input pulse causes core A to saturate again through winding N_s in the negative direction. During this time a voltage is applied to winding N_T of core B as described before, and, consequently, there is another small flux change in that core. This flux change is proportional to the flux change that occurred during reset of core A and is, therefore, inversely proportional to the system frequency. After core A saturates in the negative direction, the transistor T_s is biased off and the core is reset as before.

The incremental flux change produced on core B during each sensing period following the first is proportional to the constant voltage E_c and inversely proportional to the frequency. Core B will absorb a specific number of these flux changes whereupon it will saturate in the negative direction. The time delay that has occurred during the time between the first input pulse and the saturation of core B is approximately equal to the number of these pulses that is required for saturation of core B divided by the frequency. Let us say that N of these incremental flux changes are required for saturation of core B. Knowing the magnitude of these flux changes and the saturation flux of core B, we can compute N. It will then be found that N is proportional to the frequency of the alternating voltage. Therefore, the time delay is essentially independent of frequency. Actually, a frequency dependent term $1/f$ is present in the expression for the time delay. For normal frequencies this term is negligible.

TEST RESULTS ON HIGH- AND LOW-PHASE SENSING CIRCUIT AND OVERVOLTAGE CIRCUIT

A slightly modified version of the high- and low-phase sensing circuit of Fig. 3 was subjected to tests which produced

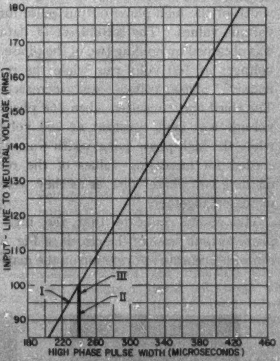

Fig. 9. Width of high-phase pulse obtained from high- and low-phase sensing circuit

I—Three-phase voltages increased together

II—Voltage of phase C is constant at 100 volts (rms). Voltages of phases A and B are increased together

III—Voltages of phases B and C are constant at 100 volts, rms. Phase A is increased

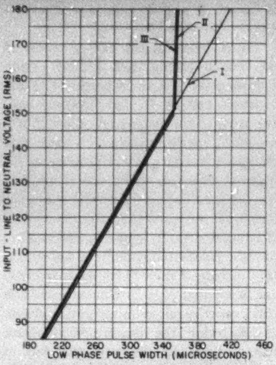

Fig. 10. Width of low-phase pulse obtained from high- and low-phase sensing circuit

I—Three-phase voltages decreased together
II—Voltage of phase C is constant at 150 volts (rms). Voltages of phases A and B are decreased together

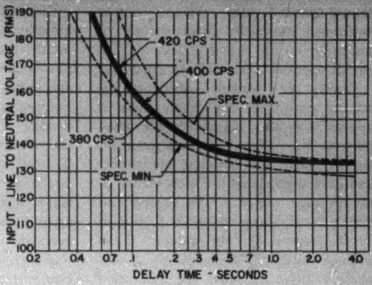

Fig. 11. Characteristics of overvoltage circuit for different system frequencies

data indicative of the accuracy of the high- and low-phase voltage sensing in a 3-phase system. High-phase sensing accuracy is indicated in Fig. 9 in which three sets of data are plotted. One set of data was obtained by increasing the three phase voltages together and recording the width of the high-phase output pulse for various values. The second set of data was obtained by holding two of the phase. voltages at 100 volts rms while the remaining phase voltage was increased. The third curve resulted when one phase voltage was kept constant at 100 volts while the high-phase pulse width was recorded for increasing values of the remaining two phase voltages as they were increased together.

The results indicate that the high-phase output pulse of the circuit of Fig. 3 contains accurate information on the magnitude of the highest phase voltage whether there are one, two, or three of these voltages which are highest. The sharp change in the slopes of the two curves that resulted when one and then two of the phase voltages were kept constant at 100 volts indicates the high sensitivity of the circuit.

The results of tests on the low-phase sensing capabilities of the circuit of Fig. 3 are shown in Fig. 10. These tests were similar to the high phase tests that have been described. It appears that the low-phase sensing is not quite as accurate as the high-phase sensing of the circuit because there is a noticeable spread between the three curves. However, it is very probable that this low-phase sensing can be improved if it is necessary for a particular specification.

The results of tests performed on the overvoltage circuit of Fig. 5 used in conjunction with the high-phase sensing circuit of Fig. 3 are shown in Fig. 11. The dashed curves represent the limits imposed by the particular specification for which the circuit was designed. The characteristics of the circuit for various frequencies of the 3-phase system are shown. The overvoltage circuit output pulse for various values of the input voltages is shown in Fig. 12. A comparison between waveforms 12(B) and 12(C) shows that the resolution of this circuit is quite high since the difference in these two waveforms is caused by a change in the high-phase voltage of less than one volt.

Combined Circuitry

When the circuits that have been described are combined to conform to the block diagram of Fig. 1, it will be found that some of the functions that were performed by a number of transistors in the separate circuits can be performed by a smaller number of transistors in the combined circuit. For example, the reset function for each of the protective circuits, which in the separate circuits requires a transistor for each circuit, requires in the combined circuit a total of only one or two transistors depending on the accuracy required. Also, the reference voltages for the circuits can be provided from a single regulated voltage supply.

Conclusion

It is felt that the following circuit concepts introduced in this paper are important:

1. The use of the memory characteristics of square-loop magnetic cores to store information as to the magnitudes of the average values of two or more alternating voltages that are out of time phase so that this information may be obtained or "read out" at any convenient time. Since pulses that have volt-second contents proportional to the average value of each of the sensed voltages may be obtained simultaneously, their volt-second content may be compared and the high-phase and low-phase pulses measured.
2. The use of the inherent capability

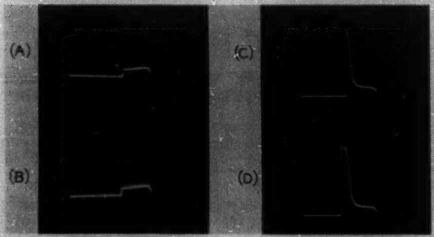

Fig. 12. Output pulse of overvoltage circuit for different values of system voltages

A—All phases = 120 volts
B—Phases A and C = 120 volts. Phase B = 134 volts
C—Phases A and C = 120 volts. Phase B = 135 volts
D—Phases A and C = 120 volts. Phase B = 155 volts

of square-loop magnetic cores to sense the total amount of volt seconds underneath the waveforms of the sensed voltages or the true average value of each of these voltages. Consequently, the average values of the sensed voltages are sensed regardless of their harmonic content.

3. The use of reactors using square-loop magnetic cores to provide a time delay that is inversely proportional to the difference between the average value of the sensed voltage and a "minimum trip" voltage which is determined by the average value of the reference pulse. The width of the reference pulse is made proportional to the period of the sensed voltage while its magnitude is regulated by a Zener diode so that the time delay produced by the core is essentially independent of the frequency of the sensed voltage.

4. The use of the memory characteristics of reactors using square-loop magnetic core material to compare the volt-second content of two voltage pulses. This function is also performed independent of frequency by making the width of the reference pulse proportional to the period of the sensed voltage.

The use of transistors or other devices as switches is necessary to perform some of the foregoing functions. In other cases, the use of transistors offers certain advantages such as; less power dissipation, fewer adjustments, smaller and lighter components, straightforward design, greater accuracy, less sensitivity to variations in parameter characteristics, etc. The circuitry described in this report has been designed with the intention of providing all of the possible advantages of this type of circuitry so as to demonstrate its full capability.

The design of transistor-magnetic circuitry to meet a particular specification may not require all of the advantages that have been mentioned and consequently the circuitry may be simplified. The decision as to how the circuit is to be designed to meet a particular specification can only be made after a thorough analysis of all of the factors involved.

Appendix I

Volt-Second Content of Output Pulse of Pulse Forming Circuit

For the first part of this analysis, refer to Fig. 2. During the sensing period when switch T_s is closed and switch T_R is open, the flux change of the pulse forming core is

$$\Delta\phi_s=\frac{1}{N_s}\int_0^{\frac{\pi}{w}} k_t e\,dt \tag{1}$$

where w is the angular frequency of the input voltage e and k_t is the ratio of transformation N_p/N_s of the input transformer. Since the average value of the input voltage is defined as

$$E_{avg}=\frac{w}{\pi}\int_0^{\frac{\pi}{w}} e\,dt \tag{2}$$

Equation 1 can be written as

$$\Delta\phi_s=\frac{k_t}{N_s}\frac{\pi}{w}E_{avg} \tag{3}$$

During the reset period when switch T_s is open and switch T_R is closed, the flux change on the core is

$$\Delta\phi_R=\frac{1}{N_R}\int^{\Delta t} E_{dc}\quad dt=\frac{1}{N_R}E_{dc}\Delta t \tag{4}$$

where Δt is the length of time between the closing of switch T_R and the saturation of the core.

Since this flux change is in the opposite direction to the flux change during the sensing period, we can solve for Δt by setting equation 4 equal to equation 3

$$\Delta t=\frac{N_R}{N_s}\frac{\pi}{w}\frac{k_t E_{avg}}{E_{dc}} \tag{5}$$

During the reset period, a voltage is induced across winding N_0 that is equal to:

$$E_o=\frac{N_c}{N_R}E_{dc} \tag{6}$$

The duration of this output voltage pulse is given by equation 5. If this voltage pulse is applied to the base of a transistor so that the transistor is saturated throughout the duration of the pulse and the load for this circuit is placed in series with the collector and the voltage E_{dc} the volt-second content of the voltage pulse applied to this load is

$$(VT)_o=\frac{N_R k_t}{2N_s}\frac{E_{avg}}{f} \tag{7}$$

It should be noted that it is not necessary to have a sine-wave input voltage for this equation to be applicable.

As a result of the foregoing analysis, it is apparent that for the 3-phase circuit of Fig. 3, the volt-second content of the voltage pulses applied to the high-phase load and the low-phase load are respectively

$$(VT)_h=\frac{N_R k_t}{2N_s}\frac{E_H}{f} \tag{8}$$

$$(VT)_L=\frac{N_R k_t}{2N_s}\frac{E_L}{f} \tag{9}$$

where E_H and E_L are respectively the average value of the high-phase input voltage and the average value of the low-phase input voltage.

Appendix II

Analysis of Overvoltage Circuit with Inverse Time Delay

The circuit that will be analyzed is that of Fig. 5. Symbols that refer to the reactor in this circuit will be primed. The high-phase output pulse of the high- and low-phase sensing circuit constitutes the input signal; the output signal is obtained in the form of high, narrow voltage pulses across resistance R_3. The reset voltage or the reference voltage E_c is a constant voltage regulated by the combination of the Zener diode Z_1 and the resistance R_1. The sensing and reset periods that will be referred to are those of the overvoltage circuit, not of the sensing circuit. In other words, the sensing period of the overvoltage circuit occurs during the same time as the reset period of the sensing circuit. Transistor T_R is biased on during the positive half cycles of the alternating voltage for a period of time approximately equal to one half the period of this voltage.

Assume initially that the overvoltage core has been reset by E_c to saturation. During the next sensing period, the high-phase output pulse of the sensing circuit which contains an amount of volt-seconds given by equation 8 of appendix I is applied to winding N_s'.

The flux change which is produced by this pulse is

$$\Delta\phi_s'=\frac{N_R k_t}{2N_s'N_s}\frac{E_H}{f} \tag{10}$$

where E_H is the average value of the highest phase voltage.

During the next reset period the voltage E_c is applied to winding N_R' for one half the period of the alternating voltage. The flux change produced during this reset period is, therefore

$$\Delta\phi_R'=\frac{1}{2N_R'}\frac{E_c}{f} \tag{11}$$

The minimum trip value of the alternating voltage will be defined as the voltage that exists when the change in flux on the overvoltage core during its sensing period is equal to the change in flux during its reset period.

We then have

$$\Delta\phi_s'=\Delta\phi_R' \tag{12}$$

Substituting from equations 1 and 2 we have

$$E_H^{o}=\frac{N_s'N_s}{N_R'N_R}\frac{E_c}{k_t} \tag{13}$$

where E_H^{o} is the value of the alternating voltage that has been defined as the minimum trip voltage and will theoretically produce an output signal from the overvoltage circuit after an infinite time delay. Therefore, we see that when the alternating voltage exceeds the minimum trip voltage, an output signal will occur after a time delay. In the following it will be shown that this time delay is essentially inversely proportional to the difference between the high-phase value of the alternating voltage and the minimum trip value of this voltage.

The net change in flux produced by one sensing period and one reset period (in other words, produced by one complete cycle of the alternating voltage) is from equations 1 and 2

$$\Delta\phi=\frac{N_R}{2N_s'N_s}\frac{k_t E_H}{f}-\frac{1}{2N_R'}\frac{E_c}{f} \tag{14}$$

After some manipulation, this becomes

$$\Delta\phi=\frac{1}{f}[E_H-E_H^{\circ}]\frac{N_RK_t}{2N_s'N_s} \tag{15}$$

The overvoltage core can absorb a specific number of these net flux changes. This number N can be determined from the following equation

$$\frac{N}{f}[E_H-E_H^{\circ}]\frac{N_Rk_t}{2N_s'N_s}=2\phi_s'-\frac{N_Rk_t}{2N_s'N_s}\frac{E_c}{f} \tag{16}$$

The amount of time that has elapsed between the time when the input voltage was instantaneously increased to a value that is greater than the minimum trip voltage and the time when the overvoltage core saturates during the sensing period is

$$T=\frac{N}{f}+\frac{1}{2f} \tag{17}$$

Solving for N from equation 7 we obtain

$$N=\frac{\dfrac{4N_s'N_s}{N_Rk_t}f\phi_s'-E_c}{[E_H-E_H^{\circ}]} \tag{18}$$

Substituting this expression in equation 17 we obtain as the expression for the time delay

$$T=\frac{\dfrac{4N_s'N_s}{N_Rk_t}\phi'_s-\dfrac{E_c}{f}}{[E_H-E_H^{\circ}]}+\frac{1}{2f} \tag{19}$$

Manufacture of Composite Cable Sheath for Telephone Exchange Cable

D. A. HUGHES
NONMEMBER AIEE

IN VARYING degrees, the insulated conductors used in telephone cables require protection from mechanical damage, moisture, and electrical disturbance. From very early in the history of telephone circuits, lead sheath provided this protection.

During and immediately following the Second World War, lead was in critically short supply. In order that telephone expansion not be limited by the lead shortage, the Bell Telephone Laboratories and the Western Electric Company developed cable sheaths which contained no lead.[1–4] A cutaway view of each of the two general types of replacing sheath is shown in Fig. 1.

To obtain sufficient sheath conductivity, aluminum proved to be the most economically usable material. Where maximum moisture protection is required, as for paper insulation, a moisture barrier of soldered steel is placed over the aluminum. For over-all protection against mechanical damage, corrosion, and moisture, an asphalt base cement is applied and a tube of high-molecular-weight polyethylene is extruded over the assembly of core, aluminum, and steel.

Polyethylene-insulated conductor, which requires less moisture protection than paper ribbon or pulp, is sheathed with aluminum and polyethylene (Alpeth sheath) in sizes from 0.22–2.38-inch core diameter. For core diameters of 0.68 inch and larger, the aluminum strip is corrugated to maintain adequate flexibility.

Paper- or pulp-insulated conductor is sheathed with aluminum, steel, and polyethylene (Stalpeth sheath) in sizes from 0.40–2.38-inch core diameter. The steel strip is always corrugated; the aluminum strip is corrugated on 0.90-inch-diameter cores and larger. This corrugation permits easier flexing of the cable with less damage to the metal strip. The range of sizes of composite sheaths is shown in Table I. In the region between 0.68-inch and 0.89-inch core diameter, the corrugated steel of Stalpeth sheath supports the aluminum sufficiently to make it unnecessary to corrugate the aluminum.

The aluminum strip used in these sheaths is 8/1000 inch thick. The steel is 7/1000 inch thick and tin plated. The polyethylene thickness is 0.045–0.110 inch. The solder is 30% tin, 70% lead. The rubber tape used over polyethylene-insulated conductor as core-to-sheath insulation is 15/1000 inch thick with 1/1000 inch of Mylar on the outer face.

Manufacture of Aluminum-Polyethylene Sheath (Alpeth)

Polyethylene-insulated conductor is twisted into pairs and subsequently into units and cable cores. Throughout the process, the conductor is exposed to normal room temperature and humidity. The completed core is fed into the Alpeth sheathing line.

The Alpeth sheathing operation proceeds as follows: First, the Mylar-faced rubber tape is applied longitudinally to give greater core-to-sheath breakdown strength and to protect the conductor

insulation from the subsequent heat of extrusion. Second, the aluminum strip, flat or corrugated, is formed around the core. Third, the polyethylene is extruded over the aluminum, cooled, and dried.

The thickness of the polyethylene jacket depends on the ratio of the volume of polyethylene extruded to the length and diameter of core over which it is extruded. Hence, for a given core, extruder screw, die setup, and temperature distribution, the output volume for each speed is measurable. The tractor capstan speed should be adjusted to maintain a constant ratio between output volume and line speed. In this process, the adjustment is made automatically.

The screw speed signal is used as the basis of comparison. When the screw speed is increased, its speed proportional signal is compared with a modified signal from the tractor capstan drive. The interaction of these signals increases the drive speed to maintain approximately constant, the ratio between extruder output volume and line speed. Hence, as the screw speed is changed, approximately constant thickness is maintained automatically.

The concentricity of the polyethylene jacket depends upon the relative position of core tube and die, and upon the temperature and pressure distribution between tube and die.

Inasmuch as the extrusion process may not be stopped while a length of cable is in the line, it is necessary to provide accumulators for the rubber tape and the aluminum tape for the time required to splice each. When the coil of rubber tape approaches a predetermined distance from runout, the speed of pay-off is increased to approximately double the line speed so that an excess of tape is forced into an accumulator. When the coil of tape runs out, there is sufficient length of tape in the accumulator so that the end of the tape can be held and cemented to the start of the new coil while the accumulator continues to supply the line. The accumulation of aluminum tape to permit the welding of the end of the expiring coil to the beginning of the new coil while the accumulator supplies the line is similar. Dual cable core supply and take-up positions are provided also to avoid stopping the extruder.

A capacitance bridge whose recording chart is graduated in thousandths of an inch of polyethylene jacket thickness, records the jacket thickness at octants around the cable.[5–7]

In addition to its use as an inspection record, this chart is used by the operator to check concentricity, roundness of core, and average thickness. He will then make appropriate adjustments if necessary and recheck.

The finished product is reeled directly upon the shipping reels at the end of the line. Before shipment the cable is tested for core-to-sheath breakdown, conductor resistance, short, cross and open circuits, dielectric strength, mutual capacitance, and capacitance unbalance. Some of these items are checked on a statistical sampling basis.

Manufacture of Aluminum-Steel-Polyethylene Sheath (Stalpeth)

Paper-pulp-insulated conductor is twisted into pairs and subsequently into units and cores at normal room temperature and humidity.[8] Paper of 0.005-inch thickness for core-to-sheath insulating strength is applied in double thickness in the cabling operation.

The completed core is dried by the passage of direct current through its conductors while in a vacuum drying dome.[9] When the core is dry, it is removed from the drying dome and placed immediately in a hot room, 130 F (degree Fahrenheit), to prevent excessive moisture absorption by the pulp. The pay-off stands from which the core is supplied to the steel and aluminum sheathing line are inside the hot room. The metal covering line, with the exception of the core pay-off stands and process reel take-up stand, is shown in Fig. 2.

For core diameters smaller than 0.90 inch, the steel tape is corrugated but the aluminum tape is flat. The flat aluminum tape is formed longitudinally around the core as the core enters the tube of the belt forming machine. This machine forms the corrugated steel tape longitudinally around the core and the aluminum.

When the core diameter is larger than 0.90 inch, both aluminum and steel tapes are corrugated. The steel tape is corrugated first and then the aluminum tape is corrugated so that its corrugations match and nest in those of the steel. The steel

tape, with the aluminum tape lying on top of it and its corrugations nesting in (in mesh with) those of the steel, is fed into the belt forming machine.[10] Both tapes are formed together against a tube around the core and a strip of paper is inserted under the lap to prevent damage of the core by heat when the seam is soldered. A forming die completes the forming of the metals around the core.

Flattened rosin core solder strip is inserted in the steel lap before it proceeds beneath the r-f (radio-frequency) inductor. The soldering position, which includes the solder inserting tool and the inductor, is shown in Fig. 3.

The area where heating is desired is the strip, approximately 1/2 inch wide, which includes the steel edges being soldered and the included solder. Under the single-turn hairpin shape inductor, heat is induced in the lap to melt the solder, fill the lap, and wet the steel edges with molten solder.

It has been observed that best soldering is attained when the steel is heated quickly to above 600 F and quenched immediately.

To control the heating in the soldering operation automatically, the energy level of the generator was adjusted manually to obtain, at each speed, the best soldering condition. For thousands of reels of cable, the relation of oscillator plate current, plate potential, plate energy, grid current, and output current to cable speed was studied. It was learned that, throughout a wide range of speed, the oscillator energy input should be proportional to the cable speed.

The designer and builder of the present 50-kw r-f generators developed a control which proportions the oscillator input to the signal from a tachometer generator. Over the required range of speed and energy levels, this response is a linear proportion.

The tachometer generator used for the cable speed proportional signal is driven by a sheave geared to the corrugations of the completed steel sheath as it leaves the tractor capstan. This signal is fed through an operator-adjusted potentiometer to the input to a 2-stage magnetic amplifier. The amplified signal feeds the saturating winding of a saturable reactor. This reactor controls the a-c input to the generator rectifier's high-voltage transformer primary.

The over-all effect of this control is to produce the proper heating effect for any cable speed while allowing the operator to adjust quickly if the cable assembly or coil distance is changed. Fig. 4 shows a block diagram of this control loop together with the solder flattening control loop which is described later.

In order to obtain uniform heating of the seam being soldered at a given speed and energy level, it is necessary to have steady coupling of the inductor with the seam. To maintain constant coupling of inductor to seam when the seam varies in position, the inductor is designed to follow the seam's position and keep a constant, adjustable, distance from the seam.[11]

This feature is required because cable cores are not truly cylindrical in shape. The twists and countertwists in the units of the core cause a cyclic variation in contour of any longitudinal section of the core. The aluminum and steel, when formed around the core, follow this contour.

At one point in the development, the use of a much lower frequency for induction heating was investigated. In some respects, the rotating source of energy is simpler and more rugged than an electronic r-f generator.

A rotating source of 10-kc energy was used to heat samples of the sheathed cable. This lower frequency is inherently more difficult to couple than the 450 kc used in previous work. Because of the coupling difficulty, a more massive output current transformer and inductor were required for comparable heating efficiency.

If 10-kc energy were used, the more massive inductor would complicate the soldering position design. The pressure shoes would have to be larger and less convenient to control. The feature of following the seam at a constant distance would be more costly to provide and more difficult to control. In present design, the 450-kc transformer and inductor are made into one structure, pivoted, and guided for ease of adjustment and to maintain constant distance between inductor and work.

The instant that the seam leaves the inductor, it is quenched with water to product the soldered seam.[12] Care must be exercised to prevent relative motion of the steel edges during cooling.

Air blasts and vacuum remove the water from the steel sheath. The sheath is stressed by rollers after it leaves the tractor capstan. During this stressing, a weak seam will open and make contact with electrodes provided and stop the operation until the operator repairs the soldered seam. The aluminum and steel sheathed core is reeled on a process reel to permit core-to-sheath insulation resistance and breakdown tests before the polyethylene is applied.

Process inspectors check continually the height and number of corrugation, quality of the aluminum and plated steel,

register, and continuity of the soldered seam.

Several factors are checked continuously by gaging methods built into the manufacturing equipment. The steel strip is checked by a photoelectric relay which stops the process if a hole of about 1/100-square-inch area or larger is detected. The width of the steel strip is also checked and the process stopped in the event of narrow strip. A break in the continuity of, or the motion of, the solder wire will also stop the line. Failure of the r-f supply or a defective soldered seam will also stop the process.

When one of these events causes the process to stop, one of the signal lights at the top of the operator's control panel indicates which event caused the stop.

To permit the use of standard round rosin core solder, a solder flattening mill has been provided on each line. The round wire is flattened to the volume required by the action of rolls whose temperature is thermostatically controlled and whose speed is proportioned to that of the cable in the line.

For this control the same speed proportional signal as used for the r-f heating control, is fed through an operator-adjusted rheostat and through a dancer arm adjusted potentiometer to a Thyratron speed control.

The roll of the dancer arm rides on a loop of the solder as it leaves the flattening mill. An additional control feature is the introduction of a booster signal when the dancer roll nears the top of its travel. If the dancer roll were permitted to reach the top, the flattened wire would be taut and likely to break. The booster signal accelerates the mill an adjustable added speed so that the dancer arm drops to the middle of its travel and removes the booster signal. At slow speeds, this cycling will continue until the cable speed signal is high enough to cause the mill to move in concert with the line.

The Thyratron control proportions the speed of the motor drive to flatten and feed precisely enough solder for the cable being sheathed.

The metal-sheathed core is paid into the polyethylene jacketing line which is shown in Fig. 5. Since the sheath has been somewhat flattened during stressing, first in the vertical axis and then in the horizontal axis, and to some degree deformed in reeling and unreeling, a sequence of forming rolls is provided. These rolls restore the original roundness of the metal sheath. Asphalt base cement is applied to fill the valleys of the corrugations and provide an adhesive between the steel and the polyethylene. The polyethylene jacket is extruded over the cement and cooled under pressure in a long tube containing water at room temperature or below. Fig. 6 is a cutaway view of the extruder head showing the feature of using vacuum to eliminate voids between the metal sheath and the polyethylene jacket. A series of high-velocity air jets dries the polyethylene. The thickness at eight successive octants is recorded by a capacitance bridge.

Fig. 6. Polyethylene extruder cutaway sketch showing application of polyethylene jacket to metal-sheathed core with vacuum eliminating voids between metal and jacket

The finished product is reeled directly upon shipping reels at the end of the line.

Before shipping, the reel of cable must pass tests for core-to-sheath breakdown strength, core-to-sheath and conductor-to-conductor insulation resistance, conductor resistance, ringout for short, cross, and open circuits, dielectric strength, a-c mutual capacitance, and capacitance unbalance. As is the case with Alpeth, some of these items are checked on a sampling basis.

Conclusion

The quantity of Alpeth and Stalpeth sheath manufactured by the Western Electric Company for telephone exchange cable has increased greatly while the quantity of lead-sheathed cable has decreased. Ninety per cent of the total output of telephone exchange cable now being manufactured by Western is composite sheath. Use has shown these replacing sheaths to be the equivalent of lead in life and more economical to manufacture and install.

A Study of the Effects of Corona on Polyethylene

ASSOCIATE MEMBER AIEE

THE DELETERIOUS effect of corona on the insulation of wires and cables subjected to high voltages has long been recognized. This basic work was undertaken to investigate the effects of corona on commercial Fawcett-type polyethylenes (branched high-pressure free-radical polymers) used as insulation in high-voltage (HV) applications. Two questions were to be answered. What are the factors involved in the design of an HV cable? What are the criteria for selecting the best polyethylene resin for this use?

These studies revealed the existence of a phenomenon which we now call "electromechanical stress cracking." It might be more descriptively termed "corona-mechanical stress cracking." This effect can be demonstrated by carefully wrapping an insulated wire spirally about a grounded mandrel and applying sufficient voltage to cause corona. The failure always occurs in the insulation which is under tension and not at a point adjacent to the mandrel as would be expected. The many variables in the mandrel test are difficult to control. A simpler test method was devised in which a film sample is stretched to give essentially uniaxial strain. Then an electrical stress is applied through the film at right angles to the mechanical strain. Relative corona life by this method correlates with that from the mandrel test. Also the stretched film arrangement allowed the use of direct electrode voltage endurance methods to study the effects of corona on insulating materials.

The investigation has involved to date approximately 400,000 sample exposure hours (approximately 44 sample-years). The following conclusions have been drawn from these data.

1. Corona life of a given polyethylene under a constant amount of corona is a function of the mechanical strain in the sample exposed. Life is decreased as the amount of mechanical strain is increased.

2. Initial mechanical stresses within the insulation can be relaxed by exposure to elevated temperatures and, thus, corona life extended.

3. The effect of voltage stress in causing failure is an indirect one; the corona it produces is the active agent.

4. Failure under corona is a surface effect and not an internal one. In the case of voids in the body of an insulation corona attack is on the inside surface of the void.

5. Corona must be suppressed to get indefinitely long life under voltage. Furthermore, corona-free electrical stresses on polyethylene insulation can be surprisingly high and still result in indefinitely long life.

6. When samples are elongated and exposed to corona, failure follows the development of surface cracks perpendicular to the direction of elongation. In an unelongated sample, the mechanism of failure is radically different; failure occurs because of progressive erosion of the insulation surface by ion bombardment which leads to decreased insulation thickness.

7. For a given voltage level causing corona, corona life of specimens in air is a strong function of the humidity. A relative humidity (RH) of 95 to 100% gives approximately 15 times longer life than dry air. The apparent reason for this somewhat surprising result is the development of a semiconducting surface layer under humid conditions which grades the fields and diminishes the corona intensity.

8. At a given voltage level, nitrogen at atmospheric pressure results in longer corona life than air. Again increased humidity augments life considerably. Corona life under our test conditions of 200 volts per mil and 50% elongation was considerably longer under 100% RH nitrogen than any other atmosphere. Again the establishment of a semiconducting layer during initial stages of corona bombardment essentially extinguished subsequent corona.

9. At a given voltage level, an environment of carbon dioxide at atmospheric pressure gave results which were again a function of humidity and were intermediate between air and nitrogen.

Paper 59-800, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 20, 1959; made available for printing May 15, 1959.

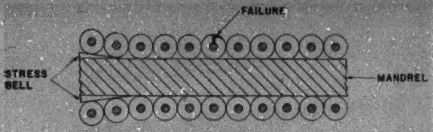

Fig. 1. Cross section of a typical failure

10. The addition of small amounts of carbon black to the polyethylene to improve resistance to weathering decreases corona life.

Implications for the Manufacturer and Users of Cables

The work described here is primarily basic research and the test specimens bear little physical resemblance to cable insulation. However, the data obtained and the conclusions drawn are directly applicable to the design and manufacture of cable. What does this information mean in cable manufacture and use?

1. Cables should be designed to be free from corona under service conditions. This means absence of either internal voids or space where corona can occur next to strand or shield.

2. The existence of the electromechanical stress-crack phenomenon means that: (*a*) Fabrication by the cable manufacturer should be carried out to give an absolute minimum of residual strain, so that the insulation will have maximum resistance to any possible corona. (*b*) The user might take steps to relax the stresses caused by bends and installation handling. This can be done by heating the cable by conductor resistance losses prior to voltage application. Even if this is not done, however, serious damage is not likely to occur since both time and temperature lead to relaxation.

3. Black jacket stock should not generally be considered as a primary insulation.

4. The improved life in nitrogen as compared with air suggests advantages for nitrogen pressure-type cables for the higher voltage levels. The use of moisture could also be considered if investigation shows that its presence is not harmful to the metal elements of the cable.

Background for Study

In view of the growing demand for plastics as insulating materials in HV applications, it became advisable to make a study of the corona life of these materials. Insulation is often subjected to a mechanical stress in addition to the electrical stress. This is particularly true in HV cable applications where the cable may be bent sharply, or mechanical stresses may be introduced in the insulation when 3-phase cables are twisted during construction. To the best of our knowledge, systematic measurements have never before been made on the effect of combined mechanical and electrical stresses. "Corona cutting" has been observed on rubber insulation when it is subjected to corona discharge. The cracking is accelerated when the rubber is elongated. The damage, in the case of rubber, is a function of ozone degradation, a reaction involving oxidation of the rubber molecule. This discussion will concern Alathon* polyethylene resin, a nonpolar plastic which does not fail by the same mechanism as rubber.

A series of experiments will be described in which the effects of applying both mechanical and electrical stresses, or electromechanical stress cracking, were studied. In this presentation, the concern is with voltages slightly above the corona starting voltage for the electrode system employed. There is a significant reduction in the life of the insulation due to corona.

Corona has been loosely defined as a luminous discharge. In this discussion, corona is defined as any electrically-detectable field-intensified ionization that does not result immediately in complete breakdown of the insulation-electrode system in which it occurs.

Test Data

Original Experiments

Early measurements to determine if there really is an effect of combined mechanical and electrical stresses were made on covered wire specimens wrapped on mandrels. The mandrels were 3/16-inch diameter stainless-steel rods approximately 6 inches long. Small electric stress bells were wound of plastic insulating tape leaving a $1^1/_2$-inch long section of uncovered steel on which to wrap the wire. Six mandrels were prepared and wrapped with 12 turns of no. *14* wire covered with polyethylene insulation having a wall thickness of 0.034 inch. Three of the wrapped mandrel samples were exposed to an average electrical stress of 200 volts per mil by applying 6,800 volts alternating current between the mandrel and the conductor. Corona was visible about the coils. The other three wrapped mandrels were not electrified but were stored nearby in the laboratory. The failures of the electrified specimens took place after 18, 26, and 27 hours. The damage was on the outside of the coils approximately at the point of greatest tension, not next to the mandrel which was the shortest path, as shown in Fig. 1. The three mandrels which were not exposed to the electrical stress, but had been under mechanical stress for one week (170 hours), showed no cracks.

For comparison, straight lengths of the same polyethylene-covered wire were loosely wrapped with tin foil to form an outer electrode. The same electric stress of 200 volts per mil was applied. The test was discontinued when no failures had occurred at 100 hours, compared with 18, 26, and 27 hours for the mechanically stressed samples.

This experiment was repeated many times with substantially the same results. Thus, preliminary proof was obtained of electromechanical stress cracking of polyethylene under the influence of corona.

In order to obtain reproducible data, it was found necessary to exercise care in winding the samples on mandrels. Good results were not obtained until the winding tool shown in Fig. 2 was built. With this tool, the wire was wrapped to a predetermined tension without kinking or twisting. No space was left between adjacent turns.

When the specimens were electrified at 200 volts per mil, a soft corona glow was seen around the coil when it was observed in a darkened room. No sharp point discharges were visible. The corona starting gradient was 80 volts per mil.

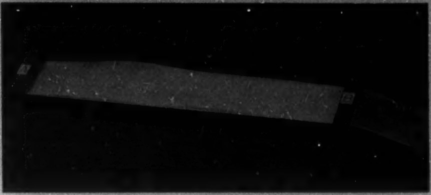

Fig. 4. Modified corona test electrode

A test rack was built to accommodate ten samples for simultaneous tests. A hood removed the ozone.

Effects of Mechanical Stress Relaxation

The effect of mechanical stress relaxation of the insulation on copper wire was investigated by wrapping 20 mandrels as previously described. Ten of these mandrels were immediately subjected to an electrical stress of 200 volts per mil. The remaining ten wrapped mandrels were held at room temperature for 200 hours before being electrified. The results in Fig. 3 show that the time to failure was longer for the specimens for which the insulating polyethylene was permitted to relax mechanically. For the latter specimens, part of the mechanical stress had been relieved.

Measurements on Films

In a mandrel test, it is very difficult to measure the amount of elongation to which a wire covering is subjected when it is bent since the forces may be triaxial. Furthermore, the amount of elongation varies throughout the cross section of the wire covering and the electrode geometry is complex; therefore, a film sample was adopted for future studies. Polyethylene films can be prepared and strained in such a fashion that the mechanical stresses are nearly uniaxial and reasonably constant throughout the cross section of the sample.

Prior to the corona studies on the mandrel wrapped samples, work was done on a direct electrode method for corona degradation measurements on insulating materials in co-operation with the ASTM (American Society for Testing Materials). The method used a rod-to-plane electrode system. The flat-plate electrode used for the ASTM study was modified. Clamps were provided so that the film could be elongated and secured under stress for the duration of the test.

Fig. 4 shows the modified electrode. The film, 2 inches wide and 14 inches long, is first secured by clamp *A* and passed through clamp *B* which is loose. The assembly is placed in a stretching rack in which the film is elongated slowly (1 inch per minute) and uniformly. The amount of stress and the elongation in the film are recorded.

The film thickness is measured and clamp *B* is tightened before the film is released from the grip. In calculating the electric stress in volts per mil, the thickness of the elongated film is used.

The lower flat-plate electrode is placed in the electrode holder (Fig. 5). The upper electrodes are constructed of stainless steel 1/2 inch in diameter and have a 1/16-inch radius on the edge. Each electrode holder is equipped with five parallel test electrodes. Each test bay holds two such electrode holders so that ten points are exposed simultaneously. Ten bays are used.

The current that flows at the time of failure is limited to 40 ma (milliamperes) by a limiting resistance network so that a large hole is not made in the sample when a test point fails. Large holes would relieve the mechanical stress on the film. An individual fusing system (Fig. 6) was devised to disconnect each individual test point automatically at the time of its failure. Current flowing from the electrode at the instant of failure passes through the voltage dropping resistance to the fuse wire. This causes a voltage difference between the chisel point and the fuse wire which gives rise to an arc burning the fuse wire which is under tension. Before the fuse wire parts, however, current passes to ground through the relay which sends a pulse to a strip chart recorder to mark the time of the failure.

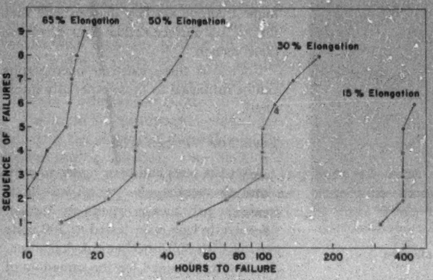

Fig. 7. Quantitative effects of electromechanical stress cracking; electric stress 200 volts/mil

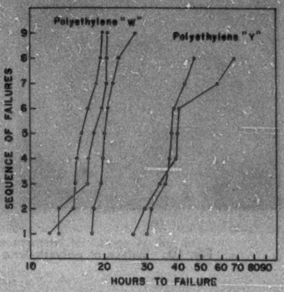

Fig. 8. Duplicability of test; measurements made with electric stress of 200 volts/mil and mechanical elongation of 50%

QUANTITATIVE EFFECTS OF MECHANICAL ELONGATION

To determine quantitatively the effect of different amounts of mechanical elongation of polyethylene resins, measurements were made on films under an electric stress of 200 volts per mil with 15, 30, 50, and 65% elongation. Fig. 7 shows that mechanical strain has a profound effect on the life of polyethylene exposed to a mild corona discharge. The samples with higher elongation had the shorter corona life. The corona energy in these experiments is low, the applied voltage being approximately 60 volts per mil above corona ignition. The experiment was repeated many times.

DUPLICABILITY OF TESTS

Fig. 8 is a plot of the life of each specimen shown in sequence of failure for five sets of samples of Du Pont polyethylene. There are three samples made from the same lot of polyethylene *W* and two samples from polyethylene *Y*. The failure times of the ten specimens of each of the three samples of *W* show little spread. There is a distinct difference demonstrated between resins *W* and *Y*. All these measurements were made under standard laboratory conditions at 200 volts per mil and 50% mechanical elongation.

Table I. Effect of Stress Annealing*

Material	Treatment	F (5/10), Hours
Polyethylene *P*	Tested as received	36.6
Polyethylene *P*	Stress relieved by annealing 6½ days at 70 C	Test stopped at 348 hours
Polyethylene *Q*	Tested as received	39.0
Polyethylene *Q*	Stress relieved as for polyethylene *P*	Test stopped at 324 hours

* Electrical stress 200 volts/mil, initial elongation 50%.

Table II. Effect of Air (50% RH) and Nitrogen (Dry) on Electromechanical Stress Cracking*

Material	F (5/10), Air, Hours	F (5/10), Nitrogen, Hours
Alathon 3, *NC-10*	36	113
Alathon 5, *NC-10*	35	140

* Room temperature; mechanical elongation 50%, electrical stress 200 volts/mil.

METHOD OF EXPRESSING RESULTS

Because of the great amount of numerical data accumulated, a convenient method was needed for compressing it. From this work and from experience on direct electrode studies on polymeric materials which have not been elongated, the time of the fifth failure out of ten specimens appears to be the most meaningful number to report. The expression F (5/10) hours is used to designate this quantity which is defined as the time in hours required for the fifth failure to take place when ten points on a sample are exposed simultaneously. Considerable time is saved by stopping the test after failure of the fifth specimen of the ten areas exposed.

EFFECT OF STRESS ANNEALING

The early measurements on the mandrel samples indicated that the life of samples was increased when some mechanical stress relaxation had taken place. A series of measurements were made on samples which were annealed after they had been mechanically stressed. The samples were mounted on the lower electrodes and clamped when elongated 50%. The electrodes and samples were placed in an oven for 150 hours at 70 C (degrees centigrade). The results are shown in Table I. The samples which were relaxed mechanically through this heat treatment exhibited a longer corona life.

A practical implication of these data is that the deleterious mechanical stresses in cables due to manufacturing operations or flexing during installation can be relieved by heat. A practical way to relieve these strains may be resistive heat loss in the conductor.

EFFECT OF AIR AND NITROGEN ON CORONA LIFE

Measurements of electromechanical stress cracking were made on many different polyethylene compositions at room

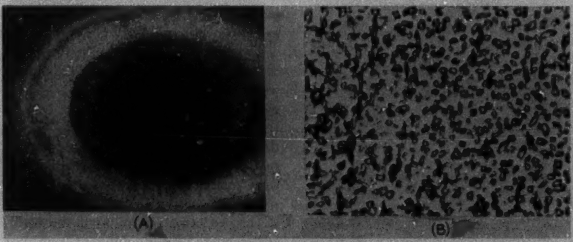

Fig. 9. Surface of polyethylene exposed to corona in air, standard laboratory conditions

temperature in both an air atmosphere (at approximately 50% RH) and a nitrogen environment at atmospheric pressure. Typical results are reported in Table II. The measurements made under an atmosphere of air always display a shorter corona life than those measured under nitrogen. In all tests which were run in air regardless of mechanical strain, a white ring was observed on the film around the outside edge of the electrode and the area subjected to the corona discharge. Many samples tested were examined under an optical microscope. Fig. 9(A) shows a typical sample (5× magnification) measured in air. The area affected by the corona appears as an oval because the film has been removed from the clamps of the lower electrode and has been allowed to relax. Fig. 9(B) is a view of the same sample but with a magnification of 200 diameters. The crystals were present on the surface of all films measured in air under standard laboratory conditions. Infrared analysis of these crystals indicated that they were oxalic acid. In addition to the crystals there are some cracks which always appear at right angle to the direction of elongation. It is of interest to note that S. I. Reynolds of the General Electric Company reported at the 1957 National Research Council Conference on Insulation that he had found oxalic acid crystals on the inside surfaces of voids in polyethylene which had been subjected to sufficient voltage to cause internal corona.

Fig. 10(A) is a view (magnified 5×) of the same material subjected to corona in a nitrogen atmosphere. This oval is smooth in appearance and does not show the crystals that are observed in the air sample. Fig. 10(B) is a 200-diameter magnification of the hazy area observed in Fig. 10(A). There are no crystals apparent. There are, however, many very fine surface cracks running transverse to the direction of mechanical stress. The mechanism of the failure under nitrogen is not yet completely understood.

ELECTRON MICROSCOPIC STUDY OF POLYETHYLENE EXPOSED TO CORONA IN DRY NITROGEN

An electron microscopic study was made on a polyethylene which was subjected to corona in a nitrogen environment at atmospheric pressure.

The results of this examination show that damage is confined to the area in the white ring formed around the periphery of the electrode. The area under the electrode was essentially unaffected. Within the white ring there were surface cracks running parallel to one another and at right angles to the direction of mechanical stress.

The mechanism of failure in dry nitrogen seems to be quite different from that in 50% RH air. As noted with optical microscopy, no oxalic acid crystals or other surface deposits are apparent. The surface cracks appearing in the region of highest corona activity demonstrate that failure is a surface rather than a volume phenomenon.

Copies of these electron micrographs can be furnished to those especially interested.

EFFECT OF WATER VAPOR

After the tests had been under way for about six months, an attempt was made to check early measurements on Alathon *3B* polyethylene resin tested at 200 volts per mil with 50% mechanical elongation. The results obtained for the same lots of film with all known variables controlled were most discouraging. The possibility of the sample slipping in the grip, variations in extrusions, and other factors which might explain the cause of the poor reproducibility were checked.

The only parameter not carefully controlled during this period was the relative humidity. Normally the tests are made under standard laboratory conditions, but during this period close control of the relative humidity was not possible because of construction work which allowed outside air to overload the air-conditioning system. A record of the relative humidity in the laboratory had been kept during the period the measurements were made. The data were correlated with humidity and tabulated in Table III. The only two measurements which do not fit are marked with asterisks. The records disclosed that these films had been cleaned with methyl alcohol before testing thus introducing another variable to the test.

Modifications were made to the test chamber so that moist or dry air could be maintained over the electrode areas. Scrubbing towers filled with water were used to wet the air which passed through the test chambers. The electrode systems were enclosed after water was poured on

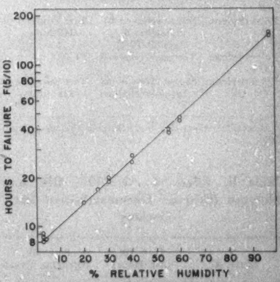

Fig. 11. Effect of humidity, measurements made with electric stress of 200 volts/mil and mechanical elongation of 50%

the floor of the box. A similar system was used to obtain dry air using Drierite in place of the water. Several measurements were made on Alathon *3B* in low (5%) and high (95%) RH. The results, along with the data obtained at the intermediate conditions, are plotted in Fig. 11.

An optical microscopic study was made of the surface of these films in the corona bombarded area. Figs. 12(A) and (B) show photomicrographs of the surface of the sample that failed in dry air. The sample failed by surface cracking, the cracks being at right angles to the direction of elongation. There is no evidence of oxalic acid. Figs. 13(A) and (B) show samples tested under a relative humidity of about 20%. Both cracks and oxalic acid crystals are observed. The oxalic acid crystals, however, are quite small and many liquid droplets appear. Figs. 13(C) and (D) are samples that were measured at 50% RH. Both cracks and oxalic acid are observed. The cracks are larger than those shown in the sample under corona at 20% RH.

The fifth failure for the sample which had been exposed to a wet-air (approximately 95% RH) atmosphere was after 155 hours. Figs. 13(E) and (F) are photomicrographs of the surface of the films. Minute cracks which were observed while the film was under tension are now hidden by wrinkles on the top surface. The surface resistivity of the area affected by the corona ranged from 10^6 (wet surface) to 10^{15} (dry surface) ohms per square compared to 10^{11} ohms per square for the area where there had been no corona.

The value of dissipation factor through the film in the area of corona bombardment was determined to be less than 0.0001 at 1 kc, indicating little or no volume effect.

EFFECT OF WET NITROGEN ON CORONA LIFE

Because such a great difference was found between wet and dry air, the effect of humidity on life in a nitrogen atmosphere was investigated by using nitrogen at 95% RH in place of air. A phenomenally long life was obtained for Alathon *3B* under a stress of 200 volts per mil. No failures had been recorded at 575 hours. To accelerate failure, the voltage was increased by 50%; four of the ten samples failed shortly and the remaining six did not fail in an additional 265 hours. The voltage was next raised to 400 volts per mil; two samples failed immediately, three within 40 hours, and the lone survivor had not failed before the test was discontinued after 120 hours at

this voltage. The results of the experiment are shown graphically in Fig. 14 which is a plot of the sequence of failures as a function of the hours to failure. The upper plot is a record of the applied voltages. These data are for individual test points.

The variation of intensity of the corona observed in a wet nitrogen atmosphere is very interesting. During the corona life measurements, the presence of corona on the sample was checked with a radio tuned to 1 mc (megacycle) and placed close to the test bay. One great difference existed between this test and previous tests. Shortly after the experiment was started, say about 1 hour, the radio ceased to indicate a noise caused by corona. No visual indication of the corona at the electrodes was observed. Periodically the radio did indicate corona bursts of several seconds duration and corona was visible at some test points during this time. This action occurred approximately every 5 minutes.

To study further this corona behavior in wet nitrogen, a new sample of Alathon *3B* was placed in the test chamber. A Biddle corona test set was used to measure corona starting voltage. The voltage was increased slowly. Corona appeared at approximately 140 volts per mil and after a few seconds at this voltage, disappeared. On raising the voltage level to 160 volts per mil corona again appeared but disappeared within a few seconds. This procedure was repeated until a steady corona discharge was finally obtained at 350 volts per mil.

These observations indicate a mechanism for longer life under wet conditions. The initial corona discharges produce a chemical reaction at the polymer surfaces to produce semiconducting films which "grade" the potentials in such a way as to eliminate the corona. After periodic corona bursts occur, the surface of the film is "healed" and the surface is given protection for a short period.

Electron Microscopic Study of Corona Damage in Moist Nitrogen

was examined in order to determine the reason for the improved corona life as compared with previous tests in dry nitrogen. Surface replicas at low (5X) magnification showed gross differences between the surface markings of the two samples. Selected areas were then examined by the electron microscopic technique to show details of the surface damage. A series of electron micrographs show that the damage to the surface of the sample measured in the wet nitrogen is more extensive and less well-defined than that to the sample measured in dry nitrogen. This fact and the observation of the characteristic tree-shaped markings support the belief that the improved test life is due to grading of potential by a semiconducting film.

Copies of these electron micrographs are available for those interested.

EFFECT OF CARBON DIOXIDE AT ATMOSPHERIC PRESSURE

The results of measurements of Alathon *3B* in carbon dioxide at atmospheric pressure are given in Table IV. The shorter life for the resin in dry carbon dioxide may be attributed to the higher corona intensity obtained in this gas than for nitrogen or air at the same voltage stress. The intermediate value obtained for wet carbon dioxide may be the result of the formation of carbonic acid on the surface of the film providing a protective semiconductive layer.

RESULTS WITH ZERO ELONGATION

Fig. 7, discussed earlier, shows the results of a series of experiments on the effect of mechanical elongation on life under corona. No data on failures were given for zero elongation since, at the 200-volts-per-mil level, sample testing was discontinued after 600 hours without any failures. Tests were begun on new samples at a stress of 300 volts per mil. The F(5/10) value (time of failure of the fifth sample of ten samples tested in parallel) at 300 volts per mil was 610 hours.

Microscopic examination of samples which failed under corona showed radically different surface conditions for polyethylene which was elongated than that which was not elongated. In the case of an elongated sample, the surface exposed to the corona discharge is covered with fine cracks which run at right angles to the direction of stretching. In the unstretched sample the area exposed to corona discharge is deeply eroded. It is believed this wearing away is caused by the impingement of gaseous ions formed in the corona discharge.

Fig. 15(A) is a slightly magnified view of the surface of an unstretched film removed from an electrode system after failure. As before, there was no corona and no change in the film under the central portion of the electrode. Failure occurred at the electrode edge.

Fig. 15(B) shows a highly magnified view of the corona bombarded area. Transverse cracks, observed with elongated samples, were not found. There are, however, oxalic acid crystals and pitted areas in the affected region. Oxalic acid crystals are more sharply defined near the edge of the bombarded area where the corona intensity was not as severe.

A section (M–M) was cut through the affected area of the sample shown in Fig. 15(A). In the magnified edge view of this section, shown in Fig. 15(C), it can be seen that the thickness in the area of most severe corona is reduced by 50% as a result of ion bombardment (erosion). The reduced thickness obviously leads to ultimate dielectric failure.

Examination of samples of the same lot of resin exposed for 600 hours to 200 volts per mil without failure showed this same effect of erosion but to a much smaller degree. A section cut radially from the corona bombarded area is shown in Fig. 16. Only a slight depression is apparent as compared to Fig. 15(C).

VOLTAGE ENDURANCE TESTING UNDER OIL

Electromechanical stress-crack measurements were made on Alathon *3B* under Dow Corning Corporation silicone fluid (dielectric constant 2.2) to study the effect of an electrical stress in the absence of corona. An initial voltage of 400 volts per mil was applied to the sample which was stretched 50%. The results of this experiment are shown in Table V. No failures were observed at 400 volts per mil after an exposure of 500 hours. The voltage was increased to 600 volts per mil, and every 500 hours thereafter an increase of an additional 200 volts per mil was made until 1,200 volts per mil (limit of the equipment) was obtained. Exposure time has exceeded 3,000 hours at 1,200 volts per mil. There have been no failures to date.

EFFECT OF ADDITION OF CARBON BLACK

Samples of Alathon *4* (polyethylene containing 2.5% carbon black) were tested at an electric stress of 200 volts per mil and under an elongation of 50%, and the results were compared to the base resin. The data show that the addition of carbon black reduces the corona life of the polyethylene to approximately one-half that of the clear resin.

Important Test Variables Which Must Be Controlled

In measuring electromechanical stress properties of polyethylene film, it has been found that careful control of the electrode weight, test voltage, humidity, and temperature are extremely important. All the samples must be of the same thickness and the surface must be clean.

EFFECT OF ELECTRODE WEIGHT

The upper electrode must make intimate contact with the film. If the electrode is too light, only a portion of its surface makes contact with the film and the area exposed to corona bombardment is not reproducible. In early experiments an electrode which had a total weight of 42 grams was used. When this weight found to be insufficient, a 90-gram electrode (1.59 square inches in area) was adopted and has been found to be quite satisfactory. The force is great enough to provide intimate contact without causing the electrode to dent the surface of the film.

EFFECT OF ELECTRODE METALS

All direct electrode measurements discussed in this study were made using electrodes of type *410* stainless steel. A series of experiments has been started to evaluate the effect on the corona life of polyethylene of electrodes fabricated from other metals.

Preliminary measurements in an atmosphere of wet air (95% RH) showed an increase of corona life from F (5/10) = 137 hours for the stainless steel electrodes to 217 hours for the copper electrodes. A heavy deposit of black copper oxide covered the latter electrode at the end of the test. The copper may catalyze the oxidation reaction on the surface of the polymer, thus assisting the formation of a protective semiconductive surface.

Need for Temperature and Humidity Control

The humidity of the atmosphere in the corona life test chamber must be carefully controlled for the reasons already indicated in detail. It is well to record the humidity and test temperature continuously. These tests have all been conducted at 23 C.

Sample Preparation

Careful sample preparation is very important. The width and thickness of the film should be the same for all samples tested. The rate of elongation must be low (1 inch per minute was used in these tests) and the amount of elongation must be accurately determined. A load cell and recorder are used with the stretching device to record the stress imparted to the film. Electrodes must be carefully cleaned and polished after each test to free them from pits or burrs.

Cleaning of Samples

The method of cleaning the sample before the test can affect the corona life. For example, cleaning polyethylene with methyl alcohol increases the life. Cleaning with distilled water will also increase life slightly. The samples used in the study were not cleaned, but were used just as formed by extrusion (except the two cases indicated in Table III). They were protected to keep the surfaces free from dust.

Projected Program

Despite the large amount of data accumulated and presented in this paper, there is much to be done to complete the study for polyethylene. In particular, methods of measuring corona energy density must be devised and this quantity related to corona resistance performance. Also the investigation will extend to other polymers.

The Design and Manufacture of Direct Burial Wire

J. L. ROBB
ASSOCIATE MEMBER AIEE

W. L. ROBERTS
NONMEMBER AIEE

OUTSIDE the high-density service areas in the central parts of cities, telephone operating companies in this country have, until recent years, found it economically necessary to use aerial distribution facilities. Open-wire construction in particular, with its high initial cost, high maintenance cost, and frequent service interruptions, offered a desirable area for development of a direct burial facility. Various efforts using rubber insulated wire with no outer protection failed, which led to the development of rubber insulated wires with neoprene jackets. Experience in certain areas indicated the need for additional mechanical and electrical protection so a light, flat ribbon steel armor is provided under the jacket in certain types of this wire.

No. *16* Awg (American wire gage) copper conductors are used in these wires and this factor, coupled with the costs of the rubber and neoprene, results in a fairly costly product which economically prevents its use in many situations. In view of this condition, the development of lower cost facility was started in 1956.

Performance Requirements

Engineers of the Rural Electrification Administration (REA) anticipated extensive use of a low-cost buried-wire facility if such could be developed and therefore established performance requirements for a wire which would meet the needs of the REA telephone program:

1. Attenuation and d-c resistance must be small enough to permit total loop lengths, including some cable plant, to reach a large proportion of subscribers, who would normally be served by 1- or 2-circuit open-wire construction, without exceeding transmission limits and supervisory limits for presently available central-office equipment. Loops of about 15 miles in length would appear to be needed.
2. All materials used in the wire should be suitable for use both above and below ground, and a life expectancy of 20 to 25 years for the wire would be necessary.
3. The wire must be armored for protection against small rodents and termites.
4. A shield for lightning protection and noise mitigation must be used and a tentative shield resistance of 15 ohms per 1,000 feet was established.
5. The wire must have a breaking strength of approximately 500 pounds to permit installation with high-speed wire-plowing equipment and to withstand ground heaving and frost cracks. A further consideration was the intended use of this wire for "aerial inserts" and for aerial drop wire.
6. The wire will be in contact with treated wood poles at terminal points and must withstand exposure to pole-treating chemi-

Paper 59-777, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 24, 1959; made available for printing April 9, 1959.

J. L. Robb and W. L. Roberts are with Superior Cable Corporation, Hickory, N. C.

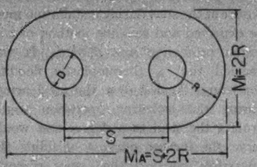

Fig. 1. Cross section of flat oval circuit

cals, particularly creosote and pentachlorophenol.

7. The cost of the wire in place must be competitive with first costs for open-wire construction.

8. Some carrier circuit potential would be desirable, but not mandatory.

A study by REA engineers indicated that a wire with no. *19* Awg copper conductors and a mutual capacitance of 0.083 μf (microfarad) per mile would meet transmission and supervisory requirements. By coincidence these are the characteristics of a no. 19 Awg cable pair. This same study proposed the use of black weather-resistant polyethylene as the insulant and offered suggested dimensions for the insulated core so proportioned that the minimum amount of insulating material would be used to achieve the desired mutual capacitance. The study also proposed the use of flat ribbon steel as a combined armor-shield-strength member.

Design of Buried Wire

Economy dictated that the two conductors in this wire be insulated in one operation, therefore a design using a parallel pair of conductors with black polyethylene extruded over them was mandatory.

SHAPE AND DIMENSIONS OF CORE

A flat oval core appeared to offer the most economic design from the standpoint of minimum amount of insulant needed to achieve the desired mutual capacitance, but since a flat steel-ribbon armor must be applied over this core a more nearly round core had to be used. Formulas for proportioning of a round shielded pair to achieve a desired mutual capacitance have been published but there was no information available on the proportioning of a core which was approximately elliptical.

Greene, Leibe, and Curtis, in an article appearing in the *Bell System Technical Journal*[1] have indicated that to obtain minimum capacitance for a flat oval shielded pair a spacing ratio of approximately 0.47 should be used. The spacing ratio is defined, in the case of the flat oval (Fig. 1), as the quotient obtained by dividing the interaxial conductor spacing (S) by the major diameter (M_a). The mutual capacitance of the flat oval circuit is very slightly greater than that of the shielded double coaxial circuit with an equal cross-sectional area. The total cross section of the flat oval circuit is

$$A=2RS+\pi R^2 \qquad (1)$$

where

$$M_a=S+2R$$

One conductor of a double coaxial circuit of equal cross section would have a radius of

$$R_1=\sqrt{\frac{1}{2\pi}(2RS+\pi R^2)}=R\sqrt{\frac{S}{\pi R}+\frac{1}{2}} \qquad (2)$$

The capacitance of the double coaxial circuit is given by the well-known relation

$$C_1=\frac{0.0194\epsilon}{\log_{10}\frac{2R_1}{d}}\ \mu\text{f per mile}$$

where d is the conductor diameter.

It is obvious from Fig. 1 that the capacitance of the flat oval circuit is less than that of a double coaxial circuit with similar insulation whose outside radius is $S/2$ (where $S<2R$). Then, if C represents the capacitance of the flat oval circuit,

$$\frac{0.0194\epsilon}{\log_{10}\frac{2R}{d}\sqrt{\frac{S}{\pi R}+\frac{1}{2}}}<C<\frac{0.0194\epsilon}{\log_{10}\frac{S}{d}} \qquad (3)$$

Furthermore, if 0.47 represents the optimum spacing for minimum capacitance, a similar oval of equal cross section, but having a spacing ratio of 0.50, would have a greater capacitance. Then

$$C<C'<\frac{0.0194\epsilon}{\log_{10}\frac{S'}{d}}$$

where

$$S'=2R'$$

Since the cross sections are equal, $2R'S'+\pi R'^2=2RS+\pi R^2$. After substituting $S'=(1.091)S$, equation 3 may then be reduced to

$$\frac{0.0194\epsilon}{\log_{10}1.165\frac{S}{d}}<C<\frac{0.0194\epsilon}{\log_{10}1.091\frac{S}{d}} \qquad (4)$$

where

$$\frac{S}{S+2R}=0.47$$

For a mutual capacitance of 0.090 μf per mile or smaller and an insulation with a dielectric constant of 2.5 or greater, the average value of those obtained from equation 4 must be correct to within ±3.5%.

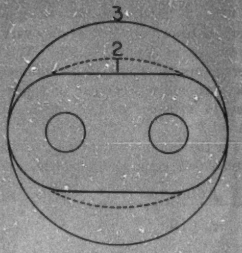

Fig. 2. Comparison of shield configurations

1—Flat oval
2—Quasi-elliptical
3—Circular

As indicated previously, the flat oval configuration presents manufacturing difficulties in the armoring operation. The quasi-elliptical cross section used may be regarded as a compromise between the flat oval circuit and the circular-shield balanced pair.

The capacitance of a balanced pair with a circular shield whose diameter is equal to the major diameter of the flat oval (Fig. 2) is given approximately by:

$$C_2\approx\frac{0.0194\epsilon}{\log_{10}\frac{2S}{d}\left[\frac{\sigma^2-1}{\sigma^2+1}\right]}$$

where

$$\frac{D}{S}=\sigma=\frac{S+2R}{S}$$

This reduces to

$$C\approx\frac{0.0194\epsilon}{\log_{10}1.276\frac{S}{d}} \qquad (5)$$

when

$$\frac{S}{S+2R}=0.47$$

For shield configurations lying within the area bounded by the flat oval and circular shields, the capacitance of the circuit is less than the upper limit indicated by equation 4, and greater than the value obtained from equation 5.

The following formula has been found to be accurate to within ±2.3% when applied to constructions with M_i/M_a ratios ranging from 0.52 to 0.75, and spacing ratios between 0.45 and 0.51:

$$C\approx\frac{0.0194\epsilon}{\log_{10}\frac{2S}{d}\left[\frac{M_a^2-S^2}{M_a^2+S^2}\right]-0.167\log_{10}\frac{M_a}{M_i}}\ \mu\text{f per mile} \qquad (6)$$

(The dielectric constant of general purpose black polyethylene may vary by as much or more than ± 2.3%. This deviation appears to be due to variation in the carbon-black content and perhaps also to moisture content of the compound.)

For the flat oval circuit with a spacing ratio of 0.47, equation 6 can be reduced to

$$C \approx \frac{0.0194\epsilon}{\log_{10} 1.146\frac{S}{d}} \text{ μf per mile} \qquad (7)$$

Equation 7 appears consistent with the inequalities expressed in equation 4. Equation 6 does not account for the shift of the optimum spacing ratio from 0.486 to 0.47, as the shield configuration changes from a circle to a flat oval.

Fig. 3 shows calculated mutual capacitance as a function of S/d for several M_t/M_a ratios with the spacing ratio fixed at 0.47.

Capacitance and Resistance Unbalance

When buried wire is used in the field, it must be anticipated that open-wire circuits and drop wires will be connected to the buried wire and therefore noise voltages induced in these facilities will be impressed on the buried wire. To minimize the effects of these noise voltages, capacitance unbalance to the shield and conductor resistance unbalance must be held to low levels.

In the previously mentioned rubber-neoprene buried wire, a capacitance unbalance maximum of 500 μμf per 1,000 feet is permitted. This seemed to be a reasonable figure and was adopted for the polyethylene insulated wire. In the case of the rubber-neoprene wire, however, this value is met by measuring the capacitance unbalance on a completed reel of wire and then, if the maximum value is exceeded, cutting the wire at the midpoint and splicing it together again with the conductors reversed. It was felt that this procedure was not necessary with the polyethylene insulated wire since it was anticipated that precise control of the polyethylene extrusion would produce wire within the capacitance unbalance limits. Manufacturing experience, however, indicated that a higher maximum value was needed to avoid excessive rejected material so a maximum value of 750 μμf per 1,000 feet was adopted.

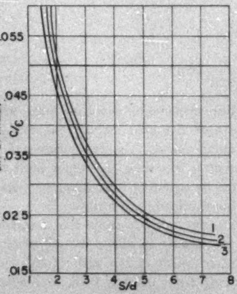

Fig. 3. Mutual capacitance graphs

1—Flat oval circuit
2—Quasi-elliptical circuit
3—Circular shielded circuit (spacing ratio = 0.47; cross sections not equal)

When this higher value of maximum capacitance unbalance was adopted, installation procedures in the field were changed to require that the two conductors of the buried wire be reversed at every terminal point. Since terminals appear, on the average, every 1/4 mile, this should control both capacitance unbalance and resistance unbalance very adequately.

Since a reversal of conductors at every terminal is required, it is necessary to identify each conductor in the buried wire. An easy and convenient means of doing this is to have one conductor tinned or plated.

The resistance unbalance limit for this wire is based on experience with other no. *19* Awg copper conductors and is set at 1.5 ohms maximum per 1,000 feet.

Armor-Shield-Strength Member

The requirements for protection against rodents and termites, along with the breaking strength requirement for the buried wire, pointed to the use of steel for this function since low cost was of such primary importance.

Based on measurements made on samples produced early in the development program, using steel armor, a shield resistance of 15 ohms per 1,000 feet appeared to be obtainable but later large scale production showed that the steel chemistry needed to meet the electrical and tensile properties was quite precise, so rather than sacrifice the electrical properties of the shield, which are at best marginal, the breaking strength requirement was reduced to 400 pounds.

Efforts to improve the conductivity of the shield and at the same time provide a measure of corrosion resistance by the use of galvanized or copper-covered steel were unsuccessful due to the cost of these materials.

It was recognized, however, that damage to the jacket of the wire and exposure of the steel during installation must be expected and so some method of corrosion protection was needed. It was decided that a thermoplastic flooding compound flooded over the steel armor during the jacketing operation would protect the steel to a degree and would serve the further purpose of filling the interstices between the armor ribbons, thereby preventing the entrance of water under the jacket. The flooding compound provided a very low-cost answer to this problem, but created another problem.

One intended use of this wire was as "aerial drop wire" in buried plant construction. Drop wires are attached to buildings and should be able to withstand a vertical flame test. The presence of the flooding compound causes the wire to be nonself-extinguishing. A type of flooding compound containing a flame retardant is currently under development which, it is believed, will overcome this difficulty.

Buried Wire Jacket

Because of the aforementioned self-extinguishing need, a polyvinyl-chloride jacket was used (see Fig. 4) This jacket provides the necessary toughness and will stand reasonable exposure to the common pole-treating chemicals, as well as provide the desired life above and below the ground.

The jacket offers no resistance to rodents or termites. The effects of soil bacteria and fungi on these jackets have not been evaluated, but no difficulties are anticipated from these sources.

Now that this wire has been in use in the field, it has developed that a method of indicating the footage on the surface of the jacket would be desirable. Since the route of the buried wire during installation is somewhat devious, conventional methods of chaining the line to determine the amount of wire used are inaccurate. Polyvinyl chloride lends itself to this type of surface marking and preliminary developments indicate that it

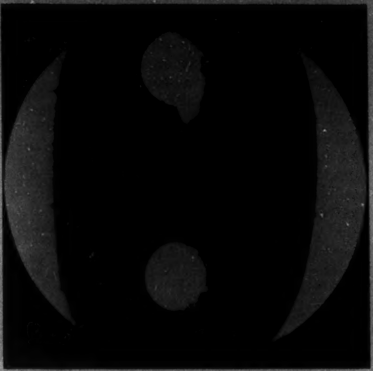

Fig. 5. Core cross section showing void formations adjacent to conductor surfaces

will be feasible to provide this marking on the wire.

Manufacture of Buried Wire

The manufacturing techniques used to produce buried wire are standard extrusion and wire-armor-serving techniques, but there are certain problems which have occurred that merit discussion.

CONDUCTORS

The application of tin or other materials as a plating on one of the copper conductors for polarity identification in this wire causes certain problems.

It is standard practice to draw wire to the finished size and then to apply the tin over this diameter. As a result, tinned conductors will be very slightly larger in diameter than bare wire of the same gage number. Also, standard specifications for tinned wire in no. *19* Awg permit a plus tolerance of 3%, while for bare wire the plus tolerance is 1%.

As a result of these factors, the tinned wire runs slightly larger than the bare wire and when these two different wires are paired, the direct capacitance to the shield is consistently higher for the tinned conductor.

This built-in unbalance, when added to the normal variations that occur in the extrusion of the core and application of the armor, results in unbalances which are greater than the permissible maximum for an undesirable percentage of the total wire produced. To overcome this, it is necessary that the tinned conductor be the same diameter as the bare conductor within close tolerances.

When two conductors of the same diameter are used, the capacitance unbalances become random rather than systematic, and the values are within limits.

Reducing the diameter of the tinned conductor, however, causes this conductor to run consistently high in resistance but still within resistance unbalance limits. This situation is, of course, corrected by the practice of reversing conductors at terminal points in the field.

EXTRUSION OF THE CORE

Considerable difficulty was experienced in verifying the calculated design for the desired mutual capacitance due to presence of voids along the conductor surface (see Fig. 5). These voids along the conductor surface tended to lower the mutual capacitance significantly. The presence of the voids in the insulation lowers the dielectric strength and cannot be controlled to yield consistent values of mutual capacitance, so it was necessary to eliminate this condition.

The effect of the voids on mutual capacitance was calculated using a simple coaxial structure with a composite dielectric since it was felt that this would be indicative of the order of magnitude of mutual capacitance variation that could be expected with the 2-conductor shielded pair.

For purposes of comparison, a coaxial type construction with a no. *16* Awg conductor and 0.100 inch wall of polyethylene with $\epsilon=2.6$ was chosen.

The potential difference formula as given in reference 2, p. 80, is:

$$V_1-V_2=\frac{\rho_L}{2}\left(\frac{1}{\epsilon_b}\ln\frac{r_2}{r_1}+\frac{1}{\epsilon_c}\ln\frac{r_3}{r_2}\right)$$

This yields a capacitance of:

$$C=\frac{0.0388}{\frac{1}{\epsilon_b}\log\frac{r_2}{r_1}+\frac{1}{\epsilon_c}\log\frac{r_3}{r_2}}\ \mu\text{f per mile}$$

where

ϵ_b = dielectric constant of void = 1
ϵ_c = dielectric constant of polyethylene, 2.6
r_1 = conductor radius, or diameter
r_2 = dielectric boundary radius, or diameter
r_3 = shield radius, or diameter

The construction cited no. *16* Awg, 0.100-inch wall, $\epsilon_c=2.6$) yields the following values:

For no void space around conductor: $C=0.144$ μf per mile.
For 0.001-inch average void space around conductor: $C=0.139$ μf per mile.
For 0.002-inch average void space around conductor: $C=0.134$ μf per mile.
For 0.003-inch average void space around conductor: $C=0.129$ μf per mile.

The capacitance decreases expressed as percentages amount to:

For 0.001-inch void space: 3.5%.
For 0.002-inch void space: 6.9%.
For 0.003-inch void space: 10.4%.

The presence of the voids seemed to be due to the presence of moisture in the carbon black used in the black polyethylene so a series of experimental runs were conducted starting with natural polyethylene and proceeding with black compounds having 0.025%, 0.041%, 0.058%, 0.075%, and 0.088% moisture contents, respectively. The natural polyethylene yielded a smooth, dense, void-free core as did the black polyethylene with a moisture content of 0.025%. The compound with 0.041% moisture content was relatively free of voids but all the other compounds resulted in gross void formation.

In those compounds where voids formed, it was found that high conductor preheat temperatures aggravated the void situation while removing the preheat caused the insulation to shrink away from the conductor creating an equally unfavorable condition. With the low moisture content compounds, the upper preheat temperature was not limited by the appearance of voids.

To control the void problem it is necessary to take steps to ensure that as little moisture as possible be absorbed by the compound prior to its use and to use extrusion techniques to remove as much moisture as possible during extrusion. Hopper dryers, fine mesh screen packs to improve mixing and increase back pressure, and tools designed to increase head pressure are all beneficial.

Conclusion

Over 1,000 miles of this type of buried wire have been installed in the field and experience to date indicates that the design objectives of this wire were sound. The carrier capabilities of this facility are quite limited but electronic developments may eliminate this shortcoming. Such developments may also extend the loop-limit capabilities of this wire.

The design of buried wire has stabilized and manufacturing problems have been solved so that this product is now available as a standard outside plant facility at a cost which compares favorably with open-wire construction in those areas where high-speed wire plows can be used. It is reasonable to expect that in coming years a substantial amount of this type of telephone distribution facility will be buried directly in the ground.

◆

Discussion

R. W. Perkinpine (American Telephone and Telegraph Company, Kansas City, Mo.): The proposed buried wire may meet a need for a relatively inexpensive wire system which could be used for rural telephone distribution purposes. In order to meet the cost objectives, sacrifices in transmission and breaking strength have had to be accepted.

In sections of the country where rodents, particularly gophers, are present this wire might not be satisfactory. Where rodent damage is a possibility, it might be preferable to consider other more costly buried wire now available. However, from the facts and figures covered in the paper, it is felt that this wire would amply meet the performance and other requirements of the REA telephone program in many sections of the country.

RECENTLY WORK has been conducted on a medium-capacity high-speed magnetic-core memory, employing small ferrite cores as the storage element. In order to perform this work, it was necessary to conduct extensive tests on the behavior of ferrite cores at high repetition rates. The experimental results permit the establishment of criteria for use of linear or coincident-current selection techniques.

The properties of special small ferrite cores which were developed for use in high-speed transistor-drive memories are discussed in this paper. The concomitant problems arising in the execution of an all-transistor approach are also considered.

Requirements for High-Speed Memories

The advent of high-speed transistor logic circuits which operate at clock rates of 1 to 10 mc (megacycles) has created a requirement for high-speed transistor-driven random-access storage units. Present commercial units operate in the 10- to 12-μsec (microsecond) range and special memories have been built operating as fast as 5 μsec per cycle. Few memories have been built which are transistor driven. Drive circuits must handle relatively high power, and for this reason it is much more complicated to design high-speed storage units than it is to design high-speed logic circuits.

There is an immediate requirement for a relatively small storage unit operating at the maximum possible speeds of transistors and magnetic cores. Secondary to this is a requirement for large memories operating at cycles faster than present memories. These will provide the bulk of the storage in a computer design.

It appears feasible to operate a fast, low-capacity memory with a 2- to 3-μsec cycle time, an intermediate capacity device with a 4-μsec cycle time, and a large memory with a 6- to 8-μsec cycle time. These cycle times are not as short as computer designers could use, but are as fast as is practicable with present transistors and magnetic cores.

AVAILABLE MATERIALS

Two basic classes of ferrite core material are presently available. The first is the rectangular loop material which is used in coincident-current core memories. This is commercially available from 1-μsec switching time to 5 μsec, and experimental quantities have been manufactured over a range from 1/4 μsec to 10 μsec. The rectangular loop materials can also be employed in linear systems and have been experimentally operated under these conditions at switching times as low as one-twentieth of a μsec. The second class of materials with less rectangular loops has been developed for use in linear systems. Much lower drive powers are required for a given switching time than is possible in rectangular materials.

MODES OF OPERATION

Two basic modes of operation are possible in high-speed storage devices. The first is the conventional coincident-current mode, while the second is the linear selec-

tion mode. Both modes may employ direct drive, diode switching, or magnetic switching. Transistors have altered the economics of memory construction in that they represent a relatively inexpensive way of providing direct drive at magnetic-core impedance levels to storage arrays. Therefore, direct drive may be used in many applications where switch drive was the only feasible approach in the past.

MEMORY CONFIGURATION

A typical coincident-current memory is 3-dimensional in nature. The address is decoded into an x-address and a y-address. The parallel bits representing the words represent the z axis. The capacity of the storage unit is xyz. The equipment in the unit is proportional to a function which can be expressed approximately as $A(x+y)+Bz$. The factor B is usually much larger than A. A linear selection memory is 2 dimensional in nature. The address is represented by one address (s). The capacity of the equipment is sz. The equipment in the unit is approximately a function of $Cs+Dz$, where D is usually larger than C.

In large systems the cubic nature of coincident-current operation yields the most economical system. In small or fast systems the linear selection mode can become more economical. This is particularly true in the case of long words, as D is usually smaller than B.

SPEED LIMITATIONS

Most high-speed core memories employ a basic 2-beat cycle. In the first beat, reading takes place and the core is set into the ZERO state. In the second beat, a writing action is performed and the core can be left in the ZERO state, or set into the ONE state.

There are three classes of speed limitations in a core memory. They are as follows:

1. Time taken to perform red tape and to propagate signals.
2. Time taken for actual magnetic-core operation.
3. Limitations due to heating of the cores and transistors at high operating rates.

LIMITATIONS DUE TO PROPAGATION

A large number of short time delays occur in any memory cycle. These are:

1. A new address is transmitted to the memory. It may be necessary to set an address register and it is always necessary to perform at least partial decoding of the address. This complete operation usually requires between 1/2 and 1 μsec.
2. The drivers are operated and these have finite rise time. Because of the very high currents employed, it is difficult to achieve rise times of less than 0.1 to 0.2 μsec.
3. If the memory is switch driven there is a propagation time in the switch itself. In diode switches this can be as low as 0.1 μsec, but in magnetic switches it is rarely lower than 0.2 μsec and can be as high as 0.5 μsec.
4. The drive currents are now applied to the memory stack and the first information output will appear some fixed time later than this. In a coincident-current memory the currents must propagate through either $x.z$ or $y.z$ cores and this introduces a delay of from 0.1 to 0.3 μsec in the average memory. In a linear selection memory there is virtually no propagation time as the read current passes through only z cores.
5. When the information signals are emitted from the matrices they must be amplified, gated, and then used to set a memory register. This usually takes between 0.3 and 0.5 μsec.

   In a coincident-current memory the drive pulse is so long that this delay is usually masked by the length of a drive pulse. In a linear selection memory very short pulses are employed and part of this delay must occur as extra cycle time.
6. The drive pulse is now cut off and there is a finite decay time. With correctly designed transistor circuits the fall time of the pulse may be between 0.2 and 0.3 μsec.
7. It is now possible to apply the digit or inhibit drive. The digit driver has a rise time of 0.1 to 0.2 μsec and this signal must propagate through $x.y$ cores in coincident-current operation, or s cores in linear selection operation. This time can vary from 0.1 to 0.5 μsec, depending on the size of the memory.
8. The write drive pulse is subject to the same delays—1, 2, and 3—as the read drive pulse. It cannot be commenced until the read drive pulse is completely finished and must not have achieved full current until delays 7 are complete.
9. There is then the period for the write drive pulse. This pulse and the digit drive pulse then decay in 0.2 to 0.5 μsec and the cycle is complete.

In a well designed equipment using available transistors it is difficult to reduce these propagation times to less than a total of about $1^1/_2$ μsec. Even in the next few years it is difficult to imagine this number being below 3/4 μsec.

TIME FOR MAGNETICS

Present 50-mil 1-μsec cores require $1^1/_2$-μsec pulses for both read and write actions. Therefore, the magnetics require 3 μsec for adequate operation. In a coincident-current cycle some overlapping of propagation time and magnetic time is possible and a 4-μsec cycle can just be achieved in small memories.

The 50-mil 1/2-μsec linear selection cores require 1/2 μsec for read and 1 μsec for write. Therefore, it is possible to achieve a 3-μsec cycle using linear selection. In very small memories it is just possible to overlap times to achieve a 2-μsec cycle.

These facts define one fundamental change-over point between coincident-current and linear selection systems. Below 4 μsec in small systems, and 5 or 6 μsec in large systems, linear selection must, at present, be employed regardless of cost.

LIMITATIONS DUE TO HEATING

Speed limitations of transistors due to overheating at high rates of operation is a well-known problem. Similar problems occur in the storage cores, but the problem is more complex in nature.

The ferrite storage cores are always strung upon a network of wires. These wires must be operated at low current density to ensure that they do not introduce heat into the system, but rather provide a conductive cooling medium for the storage cores. Ferrite cores are very poor electrical and thermal conductors, and heat dissipation within the core during an operating cycle is removed very slowly. In most present cores the operating cycle can be considered as a few μsec, whereas the thermal time constant is a few tens of milliseconds.

There are two manifestations of heating problems in ferrite core memories. First, in memories of all types, the storage properties are degraded as the temperature increases. The disturbed ONE becomes smaller and the disturbed ZERO and the nth disturb becomes larger as temperature increases. Ultimately the two types of signal become so close to each other that the memory cannot operate reliably. For an individual core, this point usually occurs somewhere in the region between 150 F (degrees Fahrenheit) and 250 F. The precise temperature depends on the material employed and is usually higher in the case of high-speed materials than in low-speed materials.

The second effect is also due to the change in storage properties as the temperature is changed. This effect occurs principally in coincident-current memories. In such memories an adequate signal to noise ratio can be obtained only if all cores in a plane have very uniform properties. Very slight local changes of temperature can degrade the performance of the plane. This effect is well known when considering the cooling of a magnetic system. Air blowing on part of a plane, and not all of it, will usually make that plane inoperative. It is not as generally realized that the same effect can occur at very high speeds of operation when a portion of a plane is scanned continuously.

This is the typical mode of operation in any random access memory used in conjunction with a computer. The result is that local heating can produce a very poor signal-noise ratio in the plane In large planes a few degrees Fahrenheit change in temperature locally can degrade performance This effect is increase as the over-all temperature of the plane is increased, thus reducing the over-all working margins.

In order to reduce the reliability of operation of a plane, it is not necessary to heat cores up to a very high temperature. A few degrees rise in a local area will be sufficiently dangerous. This effect is strictly a function of speed and program, and can be missed by many of the tests that are performed on random access memory units. The only formal test that will detect this effect is to scan a small portion of the memory very rapidly and to sample, rather rarely, cell outside that scanned area. When a failure occurs it usually appears as if the cell outside the scanned area has failed.

Some idea of the seriousness of this problem can be appreciated from the experimental fact that the normal 80-mil coincident-current cores cannot be reliably operated more rapidly than about 1 cycle every 3.6 μsec, even under the most closely controlled conditions of current and ambient temperature. The 50-mil core can just operate at 2 μsec per cycle.

Reduction of Operating Cycle

The minimum operating cycle time may be reduced by any or all of the following changes:

1. *Reduce the Size of the Core.* This increases the surface-to-volume ratio and hence improves the cooling of the core. In many transistor applications a 50-mil core is being used in place of the usual 80-mil core. Theoretically this core can operate satisfactorily under coincident-current conditions even when cycled as quickly as 3 μsec per cycle. Because of propagation limitations this core has not been operated under coincident-current conditions faster than 4 μsec per cycle.

2. *Employ a Special Mode of Operation.* In linear selection an asymetric loop is used instead of the symetric loop used in coincident-current operation, and this makes it possible to shorten the cycle time. The exact amount by which the cycle time can be shortened depends on many parameters.

3. *Improve the Thermal Properties of the Material.* This is a difficult problem but continuous progress is being made. Fortunately, the materials which show the most promise of improvement are the high-speed materials.

Cores Which Are Available for Transistor Drive

In limited applications the present 80-mil core can be transistor driven. A "low-noise" core is usually selected. This is a core which is very rectangular and which has very low *n*th disturb outputs. This minimizes the inductance that must be driven by the transistors. In high-speed applications 80-mil cores can be driven only if the memory capacity is small, or if special transistors in relatively short supply are used in the drive circuits. Small cores are much more suitable for transistor-driven systems.

The 50-mil core is 0.050 inch OD (outside diameter), 0.030 inch ID (inside diameter), and 0.015 inch thick. It is commercially available in three different materials.

ONE-μSEC COINCIDENT-CURRENT MATERIAL

The core is driven with approximately 500 ma (milliamperes) full current or 250 ma half current. Under these conditions the "knee" is above 300 ma. The core switches in almost exactly one μsec. The disturbed ONE output is about 65 millivolts and the disturbed ZERO output is about 9 millivolts. The *n*th disturb is about 1.6 mv (millivolts). These results are obtained with a current pulse which has a 0.2-μsec rise, 1.5-μsec top, and 0.2-μsec fall.

HALF-μSEC LINEAR-SELECTION MATERIAL

The core is driven with approximately 400 ma full current for read and 100 ma half current for write. The core switches during reading in about 1/2 μsec and during writing in about 1 μsec. The ONE output during reading is 75 mv and the ZERO output is 15 mv. The write outputs are about 30 mv and the half disturb output associated with the digit drive operation is about 2 mv per core. The read pulse must rise in 0.1 μsec, remain up 0.4 μsec, and fall in 0.1 μsec. The write pulse must have a top that is a little over 1 μsec in duration. If a slow rise and fall time can be permitted during writing, the half disturb output is reduced in amplitude, but this results in a longer cycle time.

FOUR-μSEC COINCIDENT-CURRENT MATERIAL

This material is not of particular value in high-speed memories as coincident-current cycles using this material must be about 20 μsec in duration. It can, however, be used in linear selection circuits to built economical transistor driven memories having cycles in the 8- to 10-μsec region.

In the coincident-current mode the material must be driven with pulses which are at least 6 μsec long at the top. The full current employed is about 220 ma. The disturbed ONE output is about 16 mv and the others are correspondingly small.

In a linear selection mode a read pulse of 2-μsec duration and 350-ma amplitude is employed. The ONE signal is 50 mv and the disturbed ZERO is 4 to 5 mv. Writing is accomplished in 4 μsec with about 220-ma drive. The write signal are small and therefore a large number of cores can be driven.

Requirements of the Transistor in the Driver Circuit

Among the most difficult problems which faces the designer of a high-speed core memory are those associated with the transistor driver circuits. Magnetic cores with short switching times require high drive currents which rise rapidly. Since the load is inductive, this places severe demands upon the forward voltage rating of the driving transistors. All three of these requirements are incompatible and tend to increase the difficulty in selecting a suitable transistor of a readily available type and at a reasonable cost.

Experiments have been performed which show that the turn-on switching time in a transistor increases approximately linearly with the current being switched. Measurements were taken in the region of 100 to 500 ma. The transistor must exhibit extremely fast switching characteristics in this range of currents. Unfortunately, transistors with faster switching speeds generally have lower collector-voltage ratings. This means that fewer cores can be driven by the transistor circuit.

These difficulties have been alleviated to some extent by the use of the 50-mil cores. It seems very unlikely that cores smaller than 50 mils can be handled by present assembly techniques. Higher speed memories of the future may consist of faster transistors and smaller "cores" in the form of thin films or twistors or storage elements of a lower energy level, such as the cryogenic device.

CONSIDERATIONS LEADING TO THE DRIVER CIRCUIT

The functions of the current driving circuit are to supply a well defined constant

Vol.

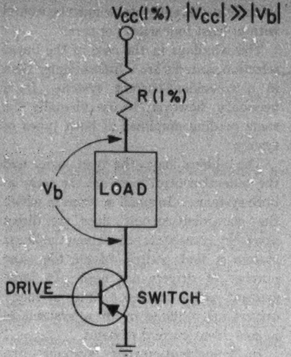

Fig. 1. Transistor switch used with precision resistor

drive current to the load regardless of the back emf (electromotive force) generated within the load, and to turn this current completely on or off with switching times within the requirements of the cores being driven.

One form of current driver makes use of the common-base transistor connection with its nearly ideal constant current output characteristics. Serious limitations exist in this type of circuit.

A considerable voltage must exist across the transistor if a wide variation of voltage drop in the load is to be accommodated. At the high current involved the power dissipation is high enough to require the use of a power transistor. Power transistors are relatively slow in switching times. Another disadvantage is that a large emitter current, which is larger than the collector current, must be switched at the input to the driver.

Another form of driver is a common-emitter stage with feedback to control the current. This also requires the use of a power transistor. With present transistors the feedback circuit is too slow to be effective. Probably the most practical approach is to employ a fast switching transistor of the 100-milliwatt class used as a nearly ideal switch. The transistor must be driven well into saturation in order to minimize the power dissipation.

In addition to the selection of a fast switching transistor, much can be done to enhance the speed of the switching circuit. It has been established[1] that a transistor can be turned on more quickly if overdriven and that the storage and turn-off times can be reduced by increasing the turn-off drive. Overdriving gives rise to an additional advantage of lowered saturation voltage. If the base can be slightly reverse biased when the transistor is to be held at cutoff, a somewhat higher collector voltage may be used. When it is inconvenient to use reverse bias the resistance of the input circuit from base to emitter must be kept as low as possible to avoid the "open base" condition.

The Driver Circuit

The highest switching speeds of currents in the several hundred ma region are obtained with small transistors used as nearly ideal switches. As previously discussed, the transistor must be driven well into saturation to keep the saturation voltage as low as possible and must be overdriven in both directions to minimize the switching times.

The transistor switch is a poor current source. Some other means must be provided to maintain a constant drive current. When the back emf V_b generated by the load is very small in relationship to the collector-voltage rating of the transistor, a precision resistor may be used in series with the transistor switch and the load across a regulated power supply, as shown in Fig. 1. This method is used in the inhibit drivers.

If the back emf is an appreciable fraction of the transistor voltage rating V_{cemax} the current-determining resistor may be returned to a much higher voltage providing a clamping diode is used to limit the voltage across the open switch; see Fig. 2.

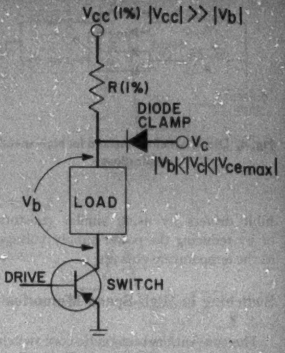

Fig. 2. Transistor switch with diode clamp

This system requires a very high supply voltage V_{cc} and a considerable amount of power must be dissipated in the resistance R. A refinement to this circuit consists of replacing the resistor with a constant current source operated from a much lower voltage.

The constant current source uses a power transistor in the common-base connection to take advantage of the pentode-type output characteristics. The power transistor is conducting at all times and receives constant current through either the clamping diode or the load. It is not required to switch the relatively high current and is therefore not limited by its slow switching speed. The combination of the constant current circuit and the clamping diode is called the current stabilizer. Two types of current stabilizers have been developed. One supplies a constant negative current and the other a constant positive current. They are called the positive current stabilizer and the negative current stabilizer.

Both of these current stabilizers are required for the bidirectional driving of the cores on a single set of windings as illustrated in (Fig. 3). The input to the transistor switch is transformer coupled so that both terminals of the switch may be made floating and so that they may be connected in either direction.

Many transistor switches may be connected to a single current stabilizer if only one of the switches is to be energized at a given time, which is the case in the operation a core memory system.

Temperature Compensation in the Current Drivers

As the temperature increases in a ferrite core memory matrix, the required coercive force of the core decreases for optimum operation. This is particularly true in a coincident-current core memory. The drive currents must be reduced as the temperature increases if a wide operating temperature range is desired. Core memories have been operated over a temperature range in excess of 80 F by using temperature compensation.

The current stabilizers have current-defining resistors with the proper positive temperature coefficient. The resistors are wound with Belco wire. Temperature compensation can be achieved in the in-

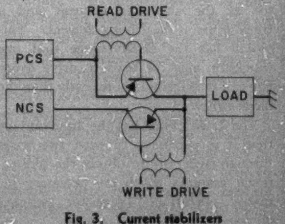

Fig. 3. Current stabilizers

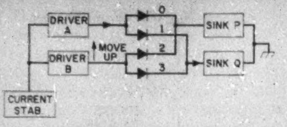

Fig. 4. Diode switch connected for high-speed applications

hibit drivers by using similar resistors or by reducing the power supply voltage as the temperature goes up.

Switching in High-Speed Memories

The conventional magnetic-core switch has considerable combinatorial advantages, but these are offset by the low overall efficiency of the switch. At high switching rates the inductance of the switch introduces voltages which are much too high to be withstood by transistors, and no form of conventional magnetic-core switch has been found which is suitable for high-speed transistor-driven applications. It is possible to construct a switch using linear transformers and diodes. This is sufficiently efficient for use in high-speed applications. However, the voltage and current levels required by the matrix stack is usually the desired operating levels of the transistor and therefore the linear transformer serves no useful purpose.

A simple form of diode switch can be employed. The manner in which this switch is connected into this system is illustrated in Fig. 4.

For each polarity, the system employs n drivers, denoted by A, B, etc., and m current sinks, denoted by P, Q, etc. Such a system can drive $m.n$ matrix lines and requires the use of $m.n$ diodes. In the illustration, current is routed from the current stabilizer through driver A, then through driver Q to select line 1. The diode employed must be capable of withstanding the full voltage and current appearing at the matrix lines.

The simplest form of switch is that illustrated in Fig. 3, which uses a transistor as the switching element and a transformer as the driving element. This switch has the disadvantage that one transistor must be used to drive every line and is, therefore, more costly than the diode switch.

The diode switch has the disadvantage that it is necessary to wind two wires through each core to obtain the bidirectional currents which are necessary for matrix operation. Transistor switches do not have this disadvantage.

ADVANTAGES OF LINEAR SELECTION SYSTEMS

Linear selection operation of the memory allows the use of very short pulses; consequently, linear selection systems are inherently rapid in operation. The propagation time through the system is negligible, as only as many cores as there are bits in the word are driven at any one time. The signal-noise ratio from linear selection systems is not usually as good as from an ideal coincident-current system but, on the other hand, the signals are clear and stable and the reading operation is usually simple to perform.

The power required to drive a linear selection system is low because the number of cores that are driven is small

DISADVANTAGES OF THE LINEAR SELECTION SYSTEMS

The principal disadvantages of the linear selection system lies in the fact that it is necessary to drive as many lines as there are words in the memory. This makes the use of a diode switch almost completely essential. In medium and large size memories this diode switch introduces severe problems as leakage in diodes and recovery time make it impossible to connect very many diodes to each driver. Experiments have shown that over a reasonable temperature range, and at high speeds of operation, it is not advisable to connect more than 32 diodes to any one driver.

In a 4,096-word system it is necessary to employ 8,192 diodes, half of which must be capable of carrying up to 500 ma peak current. Theoretically, 192 drivers could be used to drive the diode switch. In practice, however, it is necessary to use 512 drivers to overcome diode leakage and recovery problems. This places a limit on linear selection systems in that they tend to become uneconomical at sizes greater than 1,024 words.

One further disadvantage of the diode switch is that it is necessay to time the drivers rather carefully because the operation of the driver and the current sink must be relatively well timed together. This close accuracy of timing is difficult to achieve in large systems.

COMPARISON BETWEEN LINEAR SELECTION AND COINCIDENT-CURRENT SYSTEMS

It is necessary to use a crudely compensated sense winding in linear selection systems. This is required to minimize noise during reading and also to reduce voltage excursions in the reading amplifier during the writing operation. For this reason both linear selection and coincident-current systems must be wound with at least four wires per core.

The windings in the case of the linear selection systems are a little simpler than in a coincident-current system. It is necessary, however, to use virtually the same reading amplifier in both types of system.

The address logic, the read logic, and the general control logic are the same in both systems. In small systems in which the coincident-current lines are direct driven by transistors or in which the linear system is diode switch driven, the same number of drivers are used. In large systems, twice or even 4 times as many drivers are required in linear systems as in coincident-current systems.

In coincident-current systems one driver type can be used to perform all drive functions; this leads to economy of manufacture and design. In a 4-μsec-cycle system this driver must deliver about 250 ma at 10 volts. In linear systems it is necessary to employ at least four types of drivers. In a 3-μsec system these must be: (a) 400-ma driver, (b) 400-ma sink, (c) 100-ma driver, (d) 100 ma sink. In some linear systems it is necessary to add a fifth type of driver which is used in the digit drive circuit.

In general, linear selection systems must be employed for cycle times below 4 μsec. Above 4 μsec there is a choice between coincident-current and linear systems. Up to 1,024 words of storage, coincident-current systems are generally more efficient for short or medium length words. When word lengths exceed 40 to 80 bits, depending upon speed, it is usually advantageous to employ a linear selection system. Above 1,024 words, even if the word length is very long, coincident-current systems are, in most cases, more efficient than linear selection systems.

Possible Transistor-Driven Memories

The general techniques described in this paper can be used to design highly efficient transistor-driven systems which are either very small and very fast or relatively large and relatively slow. Development within the scope of this paper has been aimed at producing 3 series of modular memory units.

First, a memory with a 3-μsec total cycle time which stores either 100 or 128 words of up to 80 bits each. Second, a series of memories having capacity between 1,000 and 8,192 words of length up to 80 bits each. These memories have cycle times between 6 and 8

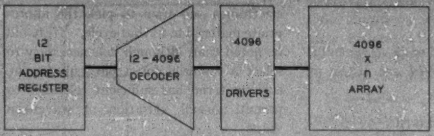

Fig. 5. Diagram for 4,096-word memory, n = number of bits in word

μsec, depending upon the total capacity. A third series of memory can be constructed using these techniques. This has a capacity of 1,024 words or less, of up to 40 bit words with a 4-μsec cycle. The first memory employs linear selection techniques, while the second and third employ coincident-current techniques throughout.

Addendum: The Behavior of Ferrite Cores at Very High Operating Rates

The operation of low-speed ferrite-core memories is relatively insensitive to changes of pulse shape. It has been determined experimentally that cores operated at high repetition rates are sensitive to pulse shape and the optimum material for a given wave shape must be chosen with some care. Cores which operate successfully with short pulses of poor wave shape will not operate successfully with pulses of the same length, but of rectangular shape. The converse is also true. The paper describes experiments that have been performed and postulates a reason for this phenomenon.

Introduction

It has been shown in many recent papers that the linear selection, or word selection, or end-fire technique, is most suitable for operating ferrite cores at high repetititon rates. Basically, this technique rejects the classical coincident-current mode and instead employs one selection wire for each word in the memory. It is necessary to employ some driver and decoding arrangement between the address register and the core array which will make it possible to select an individual word in the memory. This is illustrated in diagrammatic form for a 4,096-word memory in Fig. 5.

In practice, the drivers are introduced into the decoding matrix so that the number of drivers employed are usually no more than are used in a conventional coincident-current memory. This technique has the advantage that propagation delays associated with coincident-current memories are eliminated.

It places a much greater burden on the electronic decoding, but the use of present transistors and diodes makes it possible to perform the decoding operation rapidly. This technique also has the advantage that a new type of cycle may be used. This cycle is a characteristic feature of all linear selection systems. Two typical cycles are illustrated in Fig. 6.

Cycle-type *A* is characterized by very rapid rates of rise and fall of the current during the positive pulse. This pulse is the read pulse of the cycle. The negative pulse, or write pulse, may or may not have rapid rise and fall times but is always much smaller and longer than the positive read pulse. A ONE is inserted into a particular digit by energizing a digit drive winding. The current in this waveform is usually about two-thirds of the current available in the write selection waveform. It is clear that the normal 2-to-1 relationship of a coincident-current memory is not employed in a linear selection waveform.

In cycle-type *B* the read waveform is triangular and consists of the lowest rate of rise and fall consistent with obtaining a pulse no longer than the rectangular waveform employed in cycle *A*. The peak current in this triangular waveform is usually somewhat greater than the peak current in the equivalent rectangular waveform. The rules governing the write waveforms are the same as those in cycle-type *A*.

In practice, a large variety of waveforms can be used between these two extremes and frequently a half sine wave is used for read, and a long, low amplitude half sine wave for write. In high-speed memories the currents employed are all always quite large and it is very important to use a cycle in which the rise times are as long as possible so that relatively conventional transistors and diodes can be employed in the decoding matrices.

The output signals from any linear selection system consist of a large amplitude, short duration pulse for a read ONE, and a low amplitude, short duration pulse for a read ZERO. The write ZERO pulse is usually short and of negligible amplitude while the write ONE pulse is usually relatively very long and frequently of no greater amplitude than the read ZERO pulse. This simplifies the problem of sensing in linear selection systems as only a read ONE pulse is of large amplitude.

The principal advantages of a linear selection system are threefold. First, the pulses employed are very short; therefore, very fast cycle rates are possible. Second, only a small portion of the total flux available in the core is employed and the heat dissipation within the core is reduced considerably. This allows the core to be operated at high rates without encountering serious overheating effects. Third, the cycle employed permits the use of cores which do not have the same characteristics as those employed in coincident-current systems. It is not immediately apparent that this is an advantage. All cores employed in coincident-current systems tend to fall on or near a curve which has the characteristics that increasing currents must be supplied to the core as shorter switching times are desired. It has been found that cores which can operate successfully on a linear selection cycle can be moved off this curve so that switching times may be reduced as much as 4 times for a given current. These cores will not operate successfully in a coincident-current memory.

Testing Techniques

Linear selection memories operating at high repetition rates demand the use of drivers which develop current pulses of much greater amplitude and much shorter rise times than have yet been used in core memories. The difficulties are such that the development of adequate test equipment represents a considerable challenge. There are two principal problems encountered in designing a high-speed memory. First, a core must be obtained which can operate at sufficiently short cycle times and second, the core must be cycled very rapidly to test its performance under heating conditions. Although the thermal effects due to high repetition rates are recognized as a difficulty, the major preoccupation is that of obtaining a core which can be read and written in a very short time. Mercury relays combined with transmission lines represent a simple approach to the problem of generating short cycles of the required type. The cycles generated, however, are almost always of type *A* in Fig. 6, as effective, instantaneous rise times are available from mercury relays. There is a trend to perform all initial tests with near ideal pulses. In very small memories or in certain special types of memories, such as sequential memories, it is possible to develop drivers which will generate these near ideal pulses economically. In a random access memory it is essential that the least ideal pulse should be used, as this will have a large effect upon the economy of the decoding system.

It is both convenient and prudent to design a tester for high-speed checking which has the characteristics of cycle-type *B* in Fig. 6, as this cycle is the one that is most likely to be encountered in practice. If high-speed cores are tested on two dissimilar testers, it is found that it is not possible to correlate results obtained on both testers. Only when a short-cycle-time low-repetition-rate tester is designed to have the same characteristics as the high-rate tester is it possible to correlate performance of cores.

It has been found that not only do cores change their characteristics as heating occurs, but that, in addition, the cores are relatively sensitive to the type of cycle that is employed.

From the preliminary results that have been obtained it is obvious that testers must be used in which the complete waveform to be employed in the final memory can be simulated in testers of all types. Only if this precaution is taken can the results of testers be trusted.

Test Results

Test results obtained on developmental material known as *6914* are listed as follows:

OPERATING CHARACTERISTICS

Drive current (read) ma	500
Drive current (write) ma	280
Knee	165
Output (undisturbed ONE) mv	100
Output (disturbed ZERO) mv	16
First disturb (300/180) mv	2
*n*th disturb (300/150) mv	2
First disturb (300/180) mv	3

These results were taken using a cycle such as type *B* and it is seen that under these conditions this core is an effective storage device.

If the *6194* is tested using a cycle such as type *A*, it is found that the read ZERO signal is almost as large as the read ONE but of very short duration. In using various cycles between these two extremes it is found that in the case of this particular material the read ZERO signal is a direct function of the rise time of the read pulse. The material behaves extremely well if the rise time is sufficiently long, but very poor results are obtained on a short rise time.

Conversely a classical rectangular loop material can be tested. In this case it is found that the performance under cycle-type *A* conditions is very good. A large short read ONE signal is obtained and a small short read ZERO signal is obtained. However, when this material is tested under cycle-type *B* conditions, the read ZERO signal is reduced somewhat but the read ONE signal is reduced materially.

A large number of materials of various types have been checked and it has been found that they cover a whole gamut of characteristics between the two extremes that have been quoted. From this it is concluded that in designing a core memory it is necessary first to select the waveform which can be achieved by the electronics and then to pick the appropriate material to fit that cycle. It should be noted that, although it is necessary to select a material for a particular cycle, each material has sufficient tolerance to permit normal variation of waveform shape.

In performing these tests it was noted that the *6914* material was least sensitive to heating under rapid cycling conditions and, in general, the cores became more sensitive to heating as the rectangularity of the core increased.

At present *6914* appears to be the best material for memories of high repetition rates. It tolerates the slowest possible rise times consistent with obtaining short cycles, and also exhibits the best thermal properties.

Explanation of Phenomenon

The hypothesis developed in this section is almost certainly not correct. It does, however, provide a model by which most of the effects observed can be explained.

It is known that nucleation is an important factor in the operation of a ferrite core. It has been shown, both experimentally and theoretically, that square loop materials nucleate from relatively dispersed points and that domain wall movement then proceeds from these points. The number of points at which nucleation occurs is a function of the magneto-motive force. The higher the value of *H* the more points of nucleation. It is considered, therefore, that a rectangular loop ferrite core tends to switch, starting at the inside diameter where *H* is greatest, and then proceeds outward to the outside diameter where *H* is least.

In a linear selection operation the read current employed is much larger than the normal switching current and there is probably very active nucleation around the inside diameter; the domains then travel outward in the form of a wave toward the outside diameter. If the pulse employed is very short this action becomes interrupted so that only the inner annulus of the core is switched from

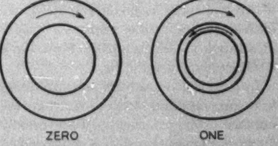

Fig. 7. Inner annulus switched from one state to another

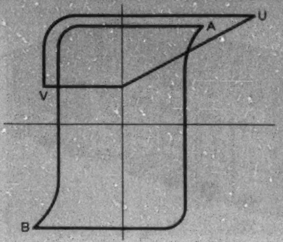

Fig. 8. Typical d-c loops using same core

one state to another. This is illustrated in Fig. 7.

During a write action this annulus is returned to its normal state so that the whole core is magnetized in one direction. This action proceeds slowly as the currents are much lower, but exists for a longer time. This action tends to maintain the bulk of the core in one direction of magnetization at all times.

Under this mode of operation only a small portion of the core is used and, therefore, the operation is analogous to employing a core that is extremely thin walled and of mean diameter, equal to the inside diameter of the core.

It is believed that an operation of approximately this type occurs when cycle-type *A* is employed. This is substantiated by the facts that the degree of magnetization of the core and the electrical performance of the core is a function of all aspects of the pulse employed. Relatively small variations of rise time, pulse duration, and amplitude, produce large variations in performance. This is to be expected if the operation employs relatively unstable flux conditions.

It is believed that another effect is present. It is possible to switch a core partially under d-c conditions. Under these conditions it is difficult to believe that only an annulus is reversed. Fig. 8 illustrates two typical d-c loops taken using the same core.

Loop *AB* is a d-c hysteresis loop of a conventional rectangular material tested under simulated coincident-current conditions. Loop *UV* is a minor loop of the same material tested under simulated linear selection conditions. Loops similar to *UV* but much smaller in all respects, are obtained under d-c conditions using *6914* material. It will be seen that the read half of the loop is that associated with point *U* and that in this part of the loop no form of coincident-current operation is possible; but if the core is pulsed with a short pulse, very rapid operation will result as permeability is very low. However, on the other half of the loop associated with point *V*, a conventional square loop form is available, and in this area the coincident-current-type operation associated with writing linear selection systems can be operated quite successfully. Material *6914* was developed using the hypothesis that a bulk effect took place in the material and that the high-speed performance of the material could be related to its d-c performance.

There are, therefore two possibilities. First, the effect may be due to switching of an annulus of the material or, secondly, the effect could be due to switching of the bulk of the material, but on a minor loop. In practice, of course, the effect is likely to be a combination of both of these. It has been found that operation of *6914* using a *B*-type cycle, is more uniform and stable than operation of rectangular loop materials using *A*-type cycle; and this would seem to confirm the theory that the effect in the *6914* material is more of a bulk effect than an annulus effect, while in rectangular loop materials the effect is more annulus than bulk.

Conclusions

The effects within the body of a ferrite core are a function of the material and of the nature of the waveforms imposed upon the material. Optimum results can be obtained only by selecting the material which most naturally fits the cycle employed. In addition, it is necessary to to employ accurate simulating techniques when testing materials as it is possible to obtain completely erroneous results by employing a waveform which differs from that of the memory under design.

A New Transistorized Negative-Impedance Telephone Repeater

R. P. DIMMER
NONMEMBER AIEE

E. L. ROBACK
NONMEMBER AIEE

WITHIN the last decade, the use of the negative impedance type of repeater in the telephone plant has proved to be a very satisfactory device to improve transmission on circuits up to about 25 miles in length. This type of repeater is both simple and low in initial cost, and when properly installed, its operating and maintenenace cost is practically negligible.

Of the two types of negative impedance repeaters available, the series type was the first to be used. This repeater adds a negative impedance in series with the transmission medium which in effect reduces the loss of the circuit. Although this type usually provides sufficient gain for most applications, it does produce some undesirable transmission characteristics such as echoes, particularly noticeable when used on multiswitched circuits. In order to reduce these effects, a shunt negative-impedance repeater was designed later to be used in combination with the series. The use of the shunt repeater also provides some additional gain. In most cases today, the use of the combination series-shunt repeater will be required to meet present-day design objectives. With both repeaters working as a team, the transmission engineer now has an excellent tool with which he can reduce the loss of most circuits satisfactorily at a cost within reason.

The extent of the application of the combination repeaters becomes largely a matter of economics. One very important economical factor which governs its use is the difficulty in line-up sometimes encountered. When facilities are not in good order, considerable restrapping may

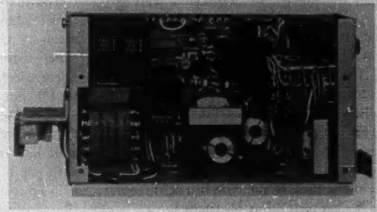

Fig. 3 (right). Interior of AT-5 repeater

be required to obtain stable repeater operation. This restrapping takes time, and requires personnel with some knowledge of strapping technique.

Present negative impedance repeaters have network components made up of many graded values of resistance, capacitance, and inductance. These are trapped in the field in a definite configuration to produce a desired gain. Many of these network components are not always used at every instance; consequently a user is penalized in cost for the parts not required. Precision components are also required to obtain reproducible gains from a number of repeaters on like facilities.

In view of these problems, it would be very desirable if a negative impedance repeater were available in which the gain could be changed by a single control, necessitating little or no strapping and which could handle most of the facilities in use today. Such a gain control technique should require the use of but a single fixed network. This is especially important today where such repeaters are placed into service by personnel unskilled in the techniques of transmission. With these objectives in mind, the General Telephone Laboratory designed a combination series-shunt negative impedance repeater, known as the Type *AT-5*, which utilizes an adjustable control on the front panel to vary the gain of the unit. This new repeater is shown in Figs. 1, 2, and 3.

Theory of Operation

Negative impedance repeaters of either type are generally composed of three parts; namely:

1. Coupling section.
2. Amplifier or converter section.
3. Network section.

The coupling section comprises either a transformer or capacitors to isolate the amplifier section from the line except for its intended voice frequency gain effects. The amplifier section comprises a fixed amplifier circuit using either vacuum tubes or transistors in either a single ended or push-pull configuration. The network section is composed of various resistors, capacitors, and inductors which can be strapped in a definite configuration to produce a required gain or equalization on the transmission medium. A block diagram of a combination repeater connected into a line between two offices is shown in Fig. 4. Note that the series repeater is placed in series with the transmission circuit, and the shunt repeater section is connected across the midpoint of the series unit in order to produce equal effects to both sides of the repeater.

A negative impedance repeater applies a negative impedance or admittance to a transmission medium as a result of a conversion of a positive impedance within the amplifier section. This positive impedance is the network; the amplifier section is the converter. Normally the

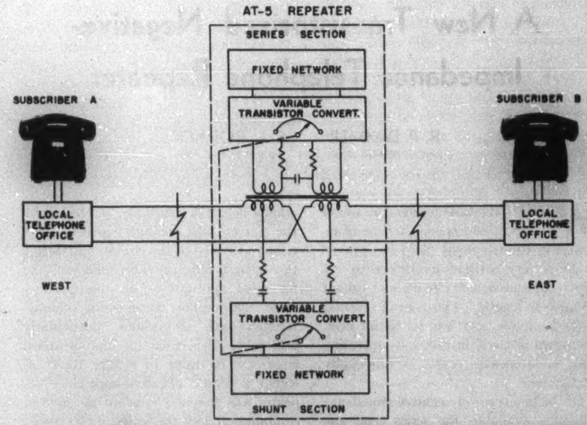

Fig. 4. Block diagram of combination repeater AT-5

Vol. 7
Pt. 1
1959

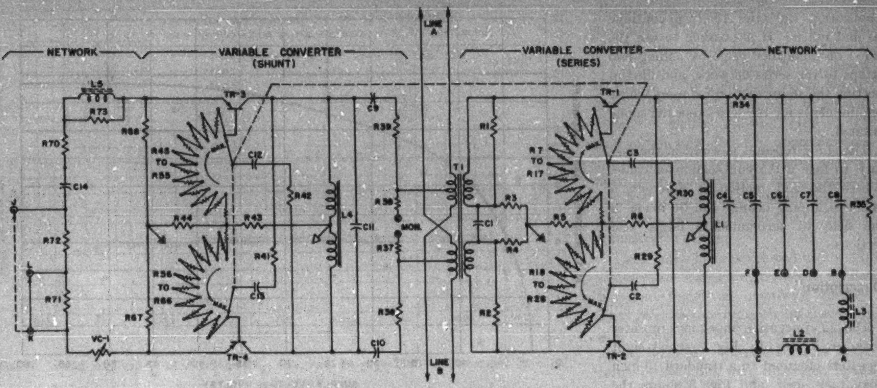

Fig. 5. Circuit of AT-5 repeater

variation of the network impedance controls the amount of negative impedance or admittance introduced on the telephone circuit. In order to use network components of reasonable size, the converter coupling section changes the effect of the impedance of the network by a fixed high-to-low ratio. In the Automatic Electric Type *AT-2* transistorized repeater, the ratio of the converter is approximately 10–1. For example; if a resistance of 10,000 ohms is connected to the network terminals, a negative impedance of approximately 1,000 ohms is reflected in series with the transmission line. This conversion is made by the amplifier section of the *AT-2*. It is also possible to use a converter with a 1-to-1 ratio, and change the ratio to 10-to-1 in the coupling device. The best method is dictated by impedance considerations. In either case the amplifier section plus the coupling device presents a constant conversion ratio factor to the network. The network is the variable element, and by changing the value of the components in it, one can obtain a variable negative impedance or gain on the transmission medium. To get various degrees of gain the strapping of many graded components is necessary. One way to eliminate strapping would be to design a repeater with all network elements variable; such a unit however, would probably be many times greater in size and undoubtedly excessive in cost. Another approach would be to use a fixed network and a variable converter. The *AT-5* repeater utilizes this principle as shown in Fig. 5.

To prove the feasibility of this method, a simple technique of varying the conversion ratio of the amplifier section of the repeater had to be found. In the *AT-2* or *AT-3* the conversion ratio of 10-to-1 is obtained by the ratio of feedback voltage on both sides of either repeater. By making these elements variable, a variable converter is obtained. This technique is shown in the circuit of the *AT-5* (Fig. 5). The gain of the various steps using this technique is shown in Fig. 6, and is very similar to that produce with a separate *AT-2* and *AT-3* combination repeater. This family of curves shows the gain steps up to the maximum of 9.8 decibels (db); however, gains above 7.0 db are not recommended in terminal applications.

To make such a repeater practical certain design assumptions have to be made; namely:

1. All cable will be loaded.
2. All loaded cable will be of the *H-88* type (88 millihenrys every 6,000 feet).
3. The end section facing the repeater will be 0.5 section.
4. It should require only one type of repeater for the most widely used gages of cable without changes or strapping.

If these assumptions are correct, then the *AT-5* will provide a voice repeater where the gain of a circuit can be changed by the simple adjustment of a front panel switch.

In most cases of transmission practice, cable will be loaded where possible before adding a repeater. In those cases where nonloaded cable is present, particularly on foreign service lines, a shunt negative impedance section cannot be used to advantage; consequently a combination repeater is seldom considered. In these

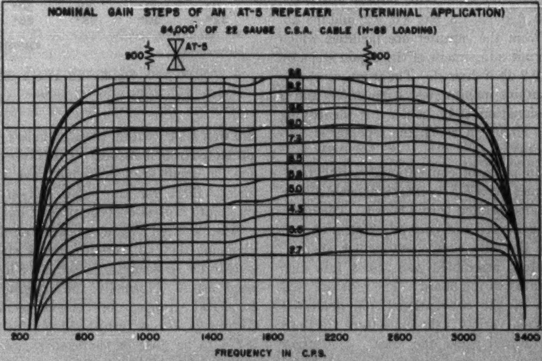

Fig. 6. Transmission characteristics of AT-5 at all gain steps

applications the series *AT-2* will continue to find usage. It is possible to use the *AT-5* on nonloaded cable by adding two straps to the series network, and disconnecting the shunt section for users whose requirements for the series repeater alone is small.

The *AT-5* repeater is wired in the factory to face a 0.5 end section of cable. Where the end section is different, a minor strapping change can be made in the field to accommodate larger end sections.

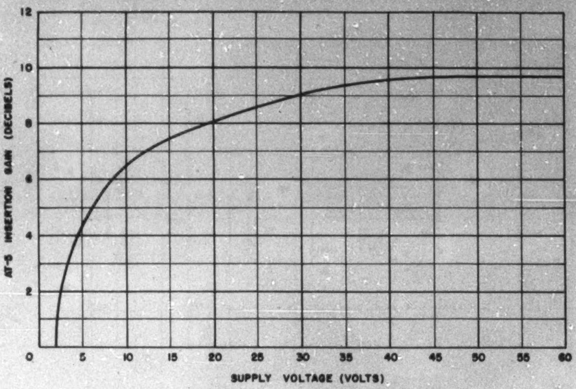

Fig. 7. Effect of supply voltage change on AT-5

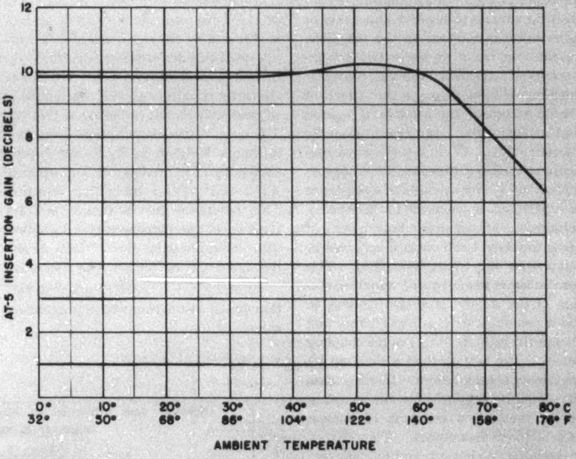

Fig. 8. Effect of ambient temperature change on AT-5

Description

The *AT-5* negative impedance repeater is shown in Fig. 1. Fig. 2 shows eight repeaters mounted on a standard 19-inch relay rack shelf, and Fig. 3 shows the interior of the unit. The unit is 2 inches wide and 9$^1/_2$ inches deep, and occupies a shelf height of 5$^1/_4$ inches. Up to eight repeaters can be mounted on a single shelf for 19-inch relay rack, or ten repeaters can be mounted on a shelf for the 23-inch rack. Each repeater is designed to slide on a track to engage an 8-point shelf jack of a type long familiar with Automatic Electric telephone equipment. These jacks are adjusted at the factory to switch both sides of the line straight through when a repeater is removed. This very desirable factor permits rapid replacement of a defective repeater if trouble should occur, without interrupting an existing conversation. The repeater jack and shelf arrangement are the same as used for the Automatic Electric Company *AT-2* and *AT-3* repeaters. Where a circuit is wired for an *AT-2*, the *AT-5* can be used directly without any changes.

The *AT-5* has an adjustable switch on the front panel which permits adjustment of gain in the following steps: 2.7, 3.5, 4.3, 5.0, 5.8, 6.5, 7.3, 8.0, 8.6, 9.2, and 9.8 db. Within the repeater are facilities which permit adjustment of these gain steps by ±0.2 db if desired. The front panel also contains monitor test connections and a designation strip holder for identifying the circuit in which the repeater is connected.

In place of conventional wiring techniques the *AT-5* repeater is assembled on a 2-sided printed wiring board. The input transformer and gain adjustment switch are the only components which are separately assembled and wired into this printed wiring board. The resistors used are of the conventional 1% deposited carbon variety; the capacitors are both metallized paper and mica. The larger capacitors are contained in tubular cylinders and mounted vertically. They are well sealed within these cylinders and protected from moisture. The transistors for the shunt section do not have heat sinks; those for the series section incorporate a press-on type of heat sink.

The printed wiring board permits changing the end section network strapping in the series unit from 0.5 to 0.8 if the need arises. Normally the repeater is furnished strapped for 0.5 end section. Terminals are also furnished to enable the *AT-5* to be used on nonloaded cable if required by adding two straps, and removing two straps within the unit.

Performance

This repeater requires no power source other than the conventional 48-volt telephone exchange battery. The unit consumes approximately 27 milliamperes at 48 volts (approximately 1.3 watts); consequently, heat radiation is not a factor as is found in vacuum-tube repeaters. The unit is not critical with changes in supply voltage as shown in Fig. 7. Between 38 and 60 volts, the gain of the unit will change only 0.2 db from its nominal value at the highest 9.8-db setting.

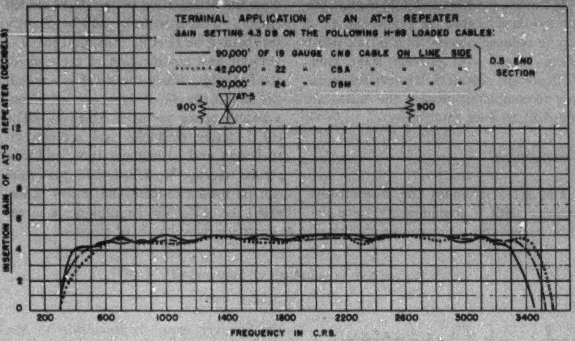

Fig. 9. Field application of AT-5 on 19-, 22-, and 24-gage H88 loaded cable (terminal application)

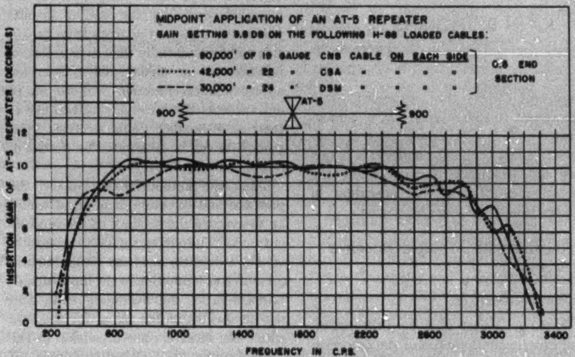

Fig. 10. Field application of AT-5 on 19-, 22-, and 24-gage H88 loaded cable (midpoint application)

The *AT-5* will drop to its 1/2 gain point with a supply voltage of 6.0 volts.

In all applications this type of repeater provides its maximum gain when installed at the middle-third of a line. The *AT-5* will provide gain equal to about 60% of the loss of the line when installed as a terminal repeater with 7.0 db as maximum. In midpoint application, gain equal to as much as 75 to 80% of the loss of the line can be utilized with 10.0 db as maximum. In order to take advantage of this midpoint characteristic, it is possible to install these units along a line (possibly mounted on poles), and supply them with voltage from the office exchange battery through a spare pair in the cable. Transistorized repeaters have a very significant merit for such applications, in that changes in supply voltage cause only small changes in the negative impedance that is presented at the input terminals. Reduction in supply voltage effects only the output (overload) capabilities of the repeater. This effect generally causes no difficulty because as the repeater is installed further from an office, its input signal is also reduced; consequently over-loading rarely occurs. The *AT-5* is capable of handling outputs of over 10 volume units before compression or distortion occurs.

Since the transistors used in the *AT-5* repeaters are of the germanium variety which are sensitive to temperature changes, the effect of high ambient temperatures must be considered. This particularly is a factor if the repeaters are to be pole mounted, or used in extreme hot climates where air conditioning is not available. The gain in the present design remains constant to 40 degrees centigrade (C) or 104 degrees Fahrenheit (F), shown in Fig. 8. The gain rises about 5% at 50 C (122 F) and drops back to normal at 65 C (149 F). At 85 C (185 F) the gain of the unit drops to approximately 1/2 of its normal value. In most applications these changes are of no significance, but in extremely hot ambient temperatures, it is well to consider this fact in the transmission design.

These units have developed no trouble under extreme high line transient, similar to those found on open-wire circuits. They have been tested with line transients in the range of 1,000 volts, and showed no sign of damage. Ringing voltages in the range of 200 volts were connected to the repeater under the most severe trouble conditions and produced no apparent change in performance.

Application

Fig. 9 shows the insertion gain of an *AT-5* when used as a terminal repeater on three gages of *H88* loaded cable, 19 *CNB*, 22 *CSA*, and 24 *DNB*. These curves are for a gain setting of 4.3 db, the maximum recommended for the facilities shown. The repeater provides approximately the same gain for each of the 3 different sizes of cable, except for a faster drop in gain at the upper frequency end on the 19 gage size. The response of Fig. 9 appears quite smooth with a resistance termination, however, when connected to phones in a normal use condition, the usual hills and valleys will appear.

Fig. 10 shows the same repeater in a midpoint application on longer circuit. In this application the *AT-5* repeater can provide gain equal to about 75% of the loss of the line up to 10 db. Here the impedance irregularities show up to a greater degree.

Installation

The installation techniques used for a *AT-5* repeater are extremely simple. Assuming the facilities are in good order, standard transmission design practices would be first considered in order to determine the maximum gain that can be inserted into the particular facility by the use of a negative impedance type of repeater. When this is determined, the adjustable control on the unit is set, and the repeater is ready for use. This assumes that the end section of the cable facing the repeater is 0.5. If this is not the case, a strap can be changed inside the unit to permit operation between 0.5 and 0.8 end section. In most cases a short- and open-circuit stability check would be made at the closest terminal. If the facility is satisfactory, the repeater would be stable for the gain set. If it is desired to refine the nominal gain of the repeater by a factor of ±0.2 db from the gain control values, provision is provided within the unit.

Because of the ease of setting gains on the *AT-5*, the singing point margin can be quickly determined.

If trouble conditions should change the return loss of a cable, the gain of the *AT-5* can be reduced quickly to a usable point where it will still provide some gain. With present repeaters, it is usually necessary to completely remove the unit, thus affording no gain whatsoever.

Conclusions

The *AT-5* provides the transmission engineer with a simplified negative impedance repeater which can be used to reduce the attenuation of any *H-88* loaded circuit. This new design can be directly substituted on circuits utilizing the *AT-2* without any modification of the rack or shelf wiring. Since the *AT-5* is one-half the size of the *AT-23* combination a considerable space saving is attained. The *AT-5* design simplifies and reduces installation and adjustment time, and as a result, average unskilled field personnel can be used to install the units. Likewise, the *AT-5* design provides one repeater for many types of facilities.

An Experimental Study of Detection in Nonstationary Noise

THOMAS R. WILLIAMS
NONMEMBER AIEE

JOHN B. THOMAS
MEMBER AIEE

THE PERFORMANCE of any system for detecting a noise-like signal in additive background noise is critically dependent on the statistics of the signal and the noise. In analyzing the performance of a given detector it is necessary to make assumptions regarding these statistics. The situations in which both the noise and the signal are Gaussian and stationary (or very nearly so) are quite numerous, and the assumption that such is the case has led to useful results. There are, however, situations where this assumption is not justified: fading signals and fluctuations in noise intensity are commonly encountered in practice.[1–7] In such cases, for short observation intervals the signal and the noise may often be regarded as Gaussian and approximately stationary and detectors can then be designed and analyzed on this assumption. However, if the observation interval is lengthened sufficiently in an attempt to increase the sensitivity of the detector, the inputs to the detector will eventually be nonstationary and the performance of the detector will differ from that expected for stationary inputs.

A theoretical analysis of the effects of nonstationary noise on the performance of a detection system consisting of an array of receivers, each of which has an output containing a stationary signal component and a nonstationary noise component, has been made recently.[8] In the present paper experimental measurements of the performance of such a system are given and it is shown that the performance is consistent with that expected from theoretical considerations. It is demonstrated that nonstationary noise can adversely affect the performance of a detector, and techniques for improving the performance of detectors operating in nonstationary noise are suggested.

Detection with Multiple Receiver Arrays

STATIONARY INPUTS

In the stationary case, both theoretical and experimental studies of the detection of signals by multiple receiver arrays have been made.[9–11] A review of the results which are pertinent to the present work follows.

Consider two nondirectional receivers (or directional receivers which have similar directivity patterns and which are aligned) which are situated in an isotropic, Gaussian, and stationary noise field; if the separation distance is sufficiently great, there will be negligible cross-correlation between the noise outputs of the two receivers.[10] To simplify the discussion, it will be assumed that the two receivers are constrained to lie at opposite ends of the diameter of a circle in the horizontal plane, and that signal sources can only lie in this plane. Assume that the signal is Gaussian and stationary and that its spectral density has the same shape as that of the noise so that predetection filtering cannot be employed to advantage. The average value of the product of the receiver outputs will be a maximum when the receiver array is broadside to the signal source and approximately zero when the receivers are in line with the signal source, again assuming the receiver separation is sufficiently great. Furthermore, for large separations, a plot of the averaged product of the receiver outputs versus the angle of the array from broadside will be essentially the autocorrelation function of the signal. Of course, the autocorrelation function will be swept out twice as the array is rotated once in the case of nondirectional receivers; this ambiguity can be eliminated by the use of directional receivers.

Thus, one method for determining the presence and direction of a signal would be to average the product of the receiver outputs. The output signal-to-noise ratio of such a detector has been computed and measured as a function of the input signal-to-noise ratio, the averaging time, and the bandwidth of the signal for the case where the receivers are broadside to the signal source.[9–11] Other methods of processing the outputs of the two receivers have been studied as well as the use of more than two receivers.[9–11]

For stationary inputs the ratio of the average signal power to the average noise power at the output of a detector is commonly used as an index of the performance of the detector, and the detection threshold occurs when this ratio is about unity. The situation is much more complex with nonstationary inputs, however, and mere measurement and tabulation of the output

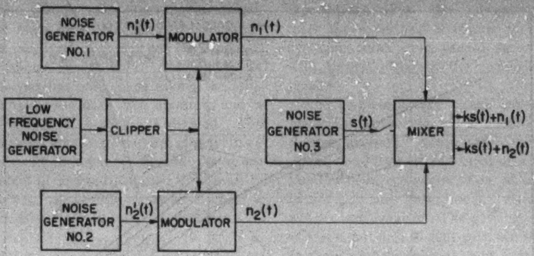

Fig. 1. System used for simulation of receiver outputs

signal-to-noise ratio as a function of the input signal-to-noise ratio does not adequately characterize the performance of a given detector. For this reason the threshold levels reported here were determined by a series of detection trials.

SIMULATED DETECTION PROBLEM

The following problem is considered here: A noise-like signal which is Gaussian and stationary is to be detected using a 2-element receiver array whose outputs are multiplied and averaged. The array is broadside to the signal source. The noise field is Gaussian and isotropic, but the noise at all points in the field is simultaneously modulated by a low-frequency random process. The receivers are sufficiently far apart that the noise in their outputs is uncorrelated, but the modulating envelopes of the two noises are identical. The signal spectral density and the noise spectral density prior to modulation have the same shape.

A block diagram of the system used in simulating the receiver outputs is shown in Fig. 1. Three identical noise generators with band-pass spectra were employed. One served as the signal; the others were amplitude-modulated by a strongly clipped low-frequency noise which was Gaussian and stationary prior to clipping. The signal and the modulated noises were added in suitable proportions in a mixer prior to application to the detector.

For the performance tests the two simulated receiver outputs were fed to a multiplier, the output of which was averaged with an *R-C* averager and displayed on an oscilloscope. The noises at the receiver outputs were present at all times. The observer controlled a switch; when a signal was present, the observer could cause it to appear or disappear from the receiver outputs by turning the switch on or off; when the signal was absent, the position of the switch made no difference in the receiver outputs. The situation thus simulated was one in which the observer could, for purposes of comparison with the background noise, effectively turn the signal on or off by, for example, turning the receiver array.

A summary of the parameters and characteristics of the signal and the noises follows. The signal was Gaussian and stationary, and had a band-pass spectrum with a Q of 10 and a center frequency of 1,000 cps (cycles per second). The unmodulated noises were similar to the signal. They were statistically independent of each other and the signal. The low-frequency noise was Gaussian and stationary, and had a band-pass spectrum with a Q of 1/2 and a center frequency of 7.5 cps; the upper and lower half-power frequencies were 18.1 and 3.1 cps, respectively. The modulating waveform was the above low-frequency noise after strong clipping. The intensities of both noises were simultaneously switched between two levels by the modulator: a high level when the low-frequency noise was positive, and a low level when it was negative. The difference in the noise power at these levels, in decibels (db), will be referred to as the depth of modulation M. The depth of modulation was varied in four steps from 0 to 18.4 db. The average noise power in each of the simulated receiver outputs was always the same; this was also the case for the signal power.

INSTRUMENTATION

The instrumentation will be described briefly. A more complete description has been given previously.[12–14] The audio-frequency noise generators utilized a gas regulator tube as the basic noise source, followed by three stages of amplification. A band-pass filter in the second stage gave the desired spectrum shape, and a cathode follower was used as the final stage to provide a low output impedance.

The low-frequency noise generator employed gamma radiation as a source of short random pulses.[13] Gamma rays excited light pulses in a scintillation crystal which were amplified with a photomultiplier tube. The amplified pulses were then passed through a band-pass filter to give the required spectrum shape. The average rate of occurrence was sufficiently large that the output noise was very nearly Gaussian. Diode clippers were used to obtain the strongly clipped low-frequency modulating voltage.

The modulators were bridge-type modulators with germanium diodes as the rectifying elements. The modulating voltage alternately switched the diodes of the bridge on and off thereby causing the a-c impedance of the modulator to switch between two values; this impedance determined the gain of an amplifier stage which amplified the noise voltage to be modulated. The output of the amplifier was therefore an audio-frequency noise whose intensity switched between two levels determined by the sign of the clipped low-frequency modulating voltage.

The multiplier used in the detector was an analog multiplier of the quarter-difference-squares type.[12] The multiplier output was averaged by a single low-pass *R-C* filter, and the filter output was observed with a d-c oscilloscope having a long-persistence screen.

EFFECTS OF NONSTATIONARY NOISE

As noted previously, a measurement of the average output signal-to-noise ratio as a function of the average input signal-to-noise ratio does not adequately describe the performance of a detector operating with nonstationary inputs. With modulated noise inputs, the expected behavior of the detector employed here would be somewhat as follows: For averaging times short compared with the average period of the modulating waveform (roughly, the reciprocal of its center frequency, or about 0.13 second), the noise output of the averager would increase and decrease in intensity with the modulating wave; after a period of high-level noise output there would follow a low-level noise period since the averager could recover quickly from the high-level input noise. The noise during the low-level periods would determine the threshold levels, since an observer could ignore the high-level noise. Of course, a small signal which existed only during a high-level period could not be detected, but the threshold of a signal occurring during a low-level period or one lasting for several periods would be determined by the low-level noise. With increasing averaging time, the averager would not recover as quickly from the high-level noise, and the threshold level might be expected to increase if the difference between the high-level and low-level noise were sufficiently great. Finally, for averaging times long compared to the modulation period, the averager would not recover at all, and the high-level noise would determine the threshold; the threshold level would then decrease with increasing averaging time.

The Experiment

Experimental Conditions and Procedure

For the detection trials, the averaged multiplier output was continuously displayed on the oscilloscope, with the total sweep time always set at slightly more than ten times the time constant of the averager. Prior to each trial the signal at the multiplier inputs was either turned on or off at random, with a probability of 1/2 for either event. The observer had at his command a switch with two positions: SIGNAL and NO SIGNAL. When the observer's switch was turned to the SIGNAL position the signal appeared at the two multiplier inputs if it had been turned on at the beginning of the trial; otherwise, the signal did not appear. At the start of the trial, the observer's switch was in the NO SIGNAL position. He was allowed to observe the oscilloscope display and turn his switch to SIGNAL once, at any instant of his choosing, then back once to NO SIGNAL, whenever he chose. The switching times and the duration of the observation were not further restricted. At the end of the trial the observer was required to decide whether or not the signal was on; he was then informed of the state of the signal and another trial was made. Although the sweep time was fixed, the observer was allowed to adjust the gain and intensity controls. In the stationary case an rms output-noise deflection of about 0.5 cm (centimeter) was usually satisfactory and the threshold signal was about the same magnitude. For short averaging times and a high level of modulation, however, the threshold was determined by low-level noise and, to see this, the gain was increased until only the low-level noise could be observed. Most of the high-level noise was off the face of the oscilloscope and, effectively, limiting was introduced at the averager output.

For a given set of parameters, the betting curve was obtained in the usual way.[15] The threshold signal level was estimated approximately, and, starting at this level, a series of 40 trials was made; after making allowance for chance successes, the proportion of correct responses was recorded. The signal power was then reduced by 1 db and another series of 40 trials was made. When the 50% point was reached, the signal was increased above the original level in 1-db steps until the 90% point was surpassed. Usually five series of trials served to determine the 90% threshold level to within about 1 db.

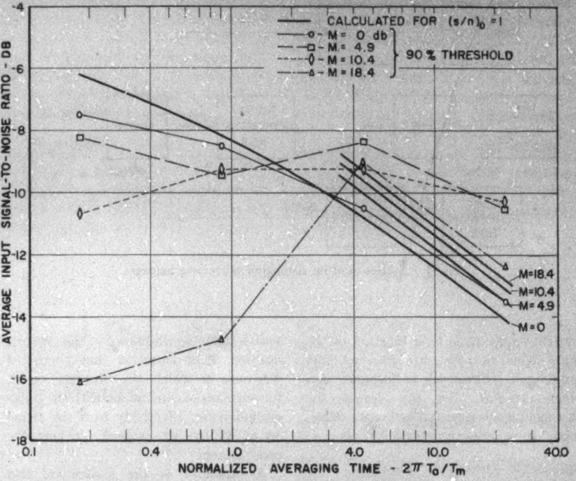

Fig. 2. Experimentally observed performance as function of averaging time; comparison with theoretical performance for long averaging times

Threshold measurements were made for four different modulation levels; starting with no modulation, as a check of the operation of the equipment, the depth of modulation was increased progressively by 4.9, 10.4, and 18.4 db. For each value of M, the 90% threshold level was determined for four averaging times ranging in multiples of 5 from 0.00382 to 0.477 second. Thus the half-power frequency of the averager was 0.334 cps for the largest averaging time and 41.8 cps for the smallest, and measurements were made both above and below the modulation center frequency. The longest averaging time used was determined primarily by drift in the system.

Results and Comparison with Theory

The experimental points are shown in Fig. 2. The results have been plotted as functions of $2\pi T_a/T_m$, where T_a is the averaging time and T_m is the reciprocal of the center frequency of the unclipped modulating noise. This is just the ratio of center frequency of the unclipped noise to the upper half-power frequency of the averager. As noted previously, an increase in the threshold levels as this ratio is increased through unity is to be expected in cases where the modulation depth is large.

In reference 8 it is shown that in the case under study here, where the inputs to the multiplier have equal signal-to-noise ratios and equal noise powers, the output signal-to-noise ratio for long averaging times will be given by equation 47 of reference 8 as:

$$(S/N)_0 = \frac{4\omega_f T_a (S/N)_i^2}{1+(\delta^2-1)^2(\delta^2+1)^{-2}} \qquad (1)$$

provided that the bandwidth of the low-frequency noise prior to clipping is much smaller than the bandwidths of the signal and the unmodulated noises. Here $(S/N)_i$ is the signal-to-noise power ratio at either of the multiplier inputs, $2\omega_f$ is the bandwidth of the signal and of the unmodulated noises in radians per second, T_a is the time constant of the averager, and δ^2 is the ratio of the upper-level noise power to the lower-level noise power. In the case studied here the bandwidth of the unclipped low-frequency noise was 15 cps and that of the signal and unmodulated noises was 100 cps. Since the former was not very small compared to the latter, the assumption made in deriving equation 1 was not strictly true. Accordingly, an analysis has been made taking the foregoing bandwidths into account, and a correction to equation 1 derived. The methods employed parallel closely those followed in reference 8, and the result differs little from equation 1; hence, in view of the length of the derivation, it will not be given here. The result is:

$$(S/N)_0 = \frac{4\omega_f T_a (S/N)_i^2}{1+0.69(\delta^2-1)^2(\delta^2+1)^{-2}} \tag{2}$$

where it has been assumed that $2\omega_f T_a$ is much smaller than unity, i.e., the bandwidth of the averager is much smaller than the bandwidth of the signal and the unmodulated noises. The depth of modulation M is given by:

$$M = 10 \log_{10}(\delta^2) \tag{3}$$

For comparison with the experimental results, the input signal-to-noise ratios necessary for an output signal-to-noise ratio of unity have been determined as functions of $2\pi T_a/T_m$ for modulation depths of 4.9, 10.5, and 18.4 db. These have been plotted as solid lines in Fig. 2. Plots have been given only for the longer averaging times where the assumptions made in deriving equation 2 are valid. In addition, a solid line giving the input signal-to-noise ratio for an output signal-to-noise ratio of unity has been plotted in Fig. 2 for the case where $M=0$. At the two longest averaging times this signal-to-noise ratio differs little from that which would be found from equation 2. Larger differences occur at the shorter averaging times for two reasons. First, at the shortest averaging time, the bandwidth of the averager was comparable to the bandwidth of the signal and the noises; a correction which affects the result only at the shortest averaging time was made to take this into account. Second, at the shortest averaging times, the a-c signal power in the detector output was a definite factor in determining the threshold level; the squared character of the signal in the output was readily apparent and helped in distinguishing the signal. Accordingly the a-c signal power, both that due to the squaring of the signal and that due to multiplication with the noise, at the detector output was counted as signal power in calculating the output signal power. This lowers the required input signal power appreciably at the two shortest averaging times and has negligible effect for the longer times. The experimental points for the stationary case are seen to be in good agreement with theoretical expectations. For the nonstationary cases the experimental results for long averaging times are in general agreement with theory, although the dispersion is greater.

The long-persistence screen employed made the averaging more effective at shorter averaging times since the observer could base his judgment on a large number of after-images, while at longer averaging times only one or two after-images were visible. The possible effect of this is not inconsistent with the results in the stationary case: at short averaging times the experimental points are below the theoretical curve while at longer averaging times they are above it. However, the differences are small and might not be significant.

It was convenient to plot the ratio of the signal power at the 90% threshold level to the average noise power in order to facilitate comparison with theory at long averaging times. Since this average noise power is determined primarily by the power at the upper level, the lowered thresholds for short averaging times shown in Fig. 2 are only a reflection of the fact that the signal was detected in these cases by observations with respect to the noise at the lower level, as was noted previously. If the ratio of the threshold signal power to the noise power at the lower level were plotted it would be found that the points all lie above those for the stationary case. To allow comparison the upper and lower noise levels referred to the average noise power are given in the following table:

Modulation Depth M, Db	High-Level Noise Power, Db	Low-Level Noise Power, Db
4.9	+1.8	− 3.1
10.4	+2.6	− 7.8
18.4	+2.9	−15.5

The general trend of the experimental results is in accordance with that expected. In particular, for the largest depth of modulation the threshold level increases quite rapidly shortly after the ratio $2\pi T_a/T_m$ increases through unity but decreases when this ratio is greater than 5. The same general behavior, though less pronounced, is exhibited at smaller depths of modulation.

It is well known that the threshold signal level for a detector operating with stationary inputs decreases with an increase of averaging time; in marked contrast, the reverse can be true with nonstationary noise as demonstrated here. This behavior results from the fact that at long averaging times it is the power of the high-level noise at the input, not the average input noise power, which determines the noise power at the detector output, and it is clear that some form of limiting might be employed to advantage.

One method of achieving limiting action would be to strongly clip both inputs to the detector prior to multiplication. The multiplier output would then be either of two voltages: a positive voltage when the two inputs were of the same polarity, or a negative voltage, equal in magnitude to the first, when the two inputs were of opposite polarity. The combination of the clippers and the multiplier forms a polarity-coincidence correlator, and the performance of such a device as a detector has been studied both theoretically and experimentally for stationary inputs.[9,10] In addition, theoretical studies of its performance have been made for various types of nonstationary noise.[8] In the cases examined it was found that, although the polarity-coincidence correlator had a slightly poorer performance for stationary noise, its performance was considerably better than that of the multiplier followed by the averager for noise which was markedly nonstationary. On the assumption that the bandwidth of the unclipped low-frequency noise is small compared to the band width of the signal and the unmodulated noise (which was very nearly true in the cases considered here), the ratio of the output signal-to-noise ratio of the polarity-coincidence correlator to that of the multiplier for equal inputs was found to be, as equation 84 of reference 8:

$$R = 0.83\left[1+\frac{1}{4}\left(\delta-\frac{1}{\delta}\right)^2\right]\left[1+\frac{1}{2}\left(\delta-\frac{1}{\delta}\right)^2\right] \tag{4}$$

where δ has been defined previously. For comparison, R in decibels has been found for the cases studied here, and is tabulated as:

Modulation Depth M, Db	R, Db
0.0	−0.8
4.9	+2.9
10.5	11.8
18.4	27.1

The use of the polarity-coincidence correlator can therefore result in a considerable improvement in performance because of the limiting action of this device.

Conclusions

The performance of a detector operating with nonstationary noise has been studied experimentally, and some of the important effects of such noise on performance have been demonstrated here. Furthermore, for long averaging times, the results obtained here have been shown to be consistent with theory. While only one class of nonstationary noise was employed in the measurements, it is reasonable to expect that the behavior of the detection system used will exhibit the same general characteristics for nonstationary noise having more complex low-frequency modulation envelopes. For moderate and high degrees of nonstationarity there will be regions where the threshold signal level will increase with increasing averaging time, and in such cases limiting or clipping prior to detection will result in lowered threshold signal levels.

Synthesis of Cable Simulation Networks

ROBERT W. DeMONTE
MEMBER AIEE

Synopsis: This tutorial paper describes a simple design procedure which permits excellent simulation of cable performance employing a symmetrical lattice network containing a small number of elements. The problem is reduced to one of synthesizing 2-terminal impedances at two frequencies. The design technique is illustrated with applications to three lengths of a particular cable. The performance covering more than 2 decades of frequency shows a design error of less than 0.5% in both real and imaginary parts of the image impedance and propagation constant of the cable. With the aid of loading coils, such networks can be used to simulate the transmission characteristics of any type of loaded cable facility having any fractional length of end section.

THE GENERAL DESIRE to improve the transmission performance of exchange area facilities in the Bell System has created needs for precision networks to simulate both image impedance and propagation constant characteristics of nonloaded and loaded cable for test purposes.

The simple design procedure described herein synthesizes these networks in a straightforward manner avoiding any cut and try procedure. This method is based on the open- and short-circuit impedances of the length of cable or on its primary constants at frequencies located at or near the edges of the desired transmission range. From these data, two 2-terminal impedances are synthesized and connected in the form of a symmetrical lattice structure. The crossarm contains 4 elements or less and the series arm 3 elements or less. Both its image or characteristic impedance and propagation constant very closely approximate that of the physical cable over the entire transmission range of frequency, which ranges from about 50 cps (cycles per second) to 10 kc.

When compared with other design procedures, this method appears superior for specified number of elements with respect to degree of simulation for given length of frequency.

Theory

Background

The classical theory on the design of simulating networks relating to uniform telephone cables has been developed by Bartlett.[1] Guillemin[2] has extended the theory by assuming a fixed number of terms used in the infinite product expansion of tanh P and proceeds to determine the deviation for a given frequency coverage. These methods appear to have little practical advantage since they assume that the primary constants do not vary with frequency and also because they require many elements in the resultant network. Johnson[3] has shown a cut and try method employing various arrangements of ladder-type networks and models of such designs have been in laboratory use for more than 25 years. When originally constructed the design requirements involved a rather narrow frequency band and adequate data on primary constants were lacking.

Zobel[4] has considered the same general problem for a length equivalent to about 10,000 feet and has a double section lattice structure containing a type of m derived 2-terminal impedance which is related directly to the cable constants (cable constants are assumed to be independent of frequency). While such a method is expected to simulate the cable performance to a high degree, it appears to require more elements than are needed by the method described herein. He has also shown an elegant method of synthesizing single constant R lattice sections to simulate the propagation constant using only the attenuation constant of the cable at two frequencies.

Paper 59-774, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 4, 1959; made available for printing April 8, 1959.

Robert W. DeMonte is with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

The writer wishes to express his appreciation to W. R. Lundry for his inspiring discussions, to Miss J. D. Goeltz for computer programing, and to Lester Hochgraf for suggesting the problem.

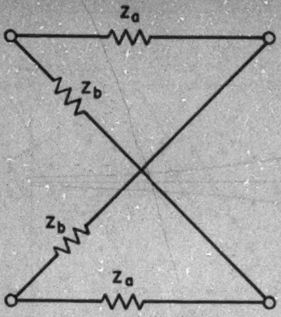

Fig. 1. Lattice representation of cable

LATTICE EQUIVALENT OF CABLE

A cable having primary constant of R, L, G, and C per unit length and length l is characterized by an image impedance

$$z_k = \sqrt{(R+jL\omega)/(G+jC\omega)} = r_k - jx_k \tag{1}$$

and the propagation constant

$$Pl = l\sqrt{(R+jL\omega)(G+jC\omega)} = \alpha + j\beta \tag{2}$$

where

$\omega = 2\pi f$ (f = frequency)
α = the attenuation constant
β = the phase shift constant

In terms of the open- and short-circuit impedance measurements z_{oc} and z_{sc}, respectively, the image impedance

$$z_k = \sqrt{z_{oc} z_{sc}} = r_k - jx_k \text{ (ohms)} \tag{3}$$

and the propagation constant

$$Pl = 10 \log_{10} \left|\frac{1+\sqrt{z_{sc}/z_{oc}}}{1-\sqrt{z_{sc}/z_{oc}}}\right| + \text{angle of} \left|\frac{1+\sqrt{z_{sc}/z_{oc}}}{1-\sqrt{z_{sc}/z_{oc}}}\right| \tag{4}$$

$$= \alpha(db) + j\beta(\text{deg.})$$

It is well known that any distributed system of length l such as a cable can be represented by a symmetrical lattice structure as shown in Fig. 1, where

$$z_a = z_{oc}\left(1-\sqrt{1-\frac{z_{sc}}{z_{oc}}}\right) = z_k \frac{\epsilon^{Pl}-1}{\epsilon^{Pl}+1} \tag{5}$$

and

$$z_b = z_{oc}\left(1+\sqrt{1-\frac{z_{sc}}{z_{oc}}}\right) = z_k \frac{\epsilon^{Pl}+1}{\epsilon^{Pl}-1} \tag{6}$$

are the series and crossarm impedances respectiely. They are also equal to the short- and open-circuit impedances of a length $l/2$.

Then

$$z_n = \sqrt{z_{ab} z_b} = r_n - \mathrm{J}x_n \tag{7}$$

and

$$Pl_n = 20 \log_{10} \left|\frac{1+\sqrt{z_a/z_b}}{1-\sqrt{z_a/z_b}}\right| + \text{angle of} \left|\frac{1+\sqrt{z_a/z_b}}{1-\sqrt{z_a/z_b}}\right| \tag{8}$$

$$= \alpha_n + j\beta_n$$

are the image impedance and propagation constants of the equivalent lattice network respectively.

Now the problem is one of determining the configuration of the network and element values for the two two-terminal impedances to approximate z_a and z_b over the desired frequency range.

METHOD OF DESIGN

Direct computations show that for short lengths of cable of 6,000 feet or less, both z_a and z_b are modestly increasing or decreasing monotonic curves over the frequency range up through 10,000 cps as shown in Figs. 2 and 3. f_1 and f_2 represent frequencies at or near the ends of the transmission band. In Fig. 2, for a cable length l_1 the curves marked r_1 and x_1 are the impedance components of z_a when it has inductive reactance. As the length is increased to l_2, that rare case is obtained when the reactive component x_2 approximates zero over the frequency range and is zero at f_2. r_2 closely approximates a constant resistance which is nearly equal to one-half of the d-c resistance of the cable. Greater lengths are represented by curves r_3 and x_3 which indicate a capacitive reactance component of z_a.

In Fig. 3, r_b and x_b are typical shapes of the components of z_b for all lengths. In the vicinity of frequency f_2, the reactance curve x_b tends to approach the zero value more rapidly for the longer lengths of cable.

The primary constants of a real cable vary with frequency. Skin effect increases the resistance and decreases the inductance. The conductance increases several hundred fold while the capacitance decreases a small amount. These variations are accounted for in the shape of the curves of Figs. 2 and 3.

Because of the simple shapes of these empirically determined graphs, when synthesized at two frequencies say f_1 and f_2, the approximant is accurate at all frequencies within the band as well as in the vicinity of its edges.

A. SYNTHESIS OF z_a

Each pair of impedance curves in Fig. 2 can be represented by a simple ratio of polynominals.

Let

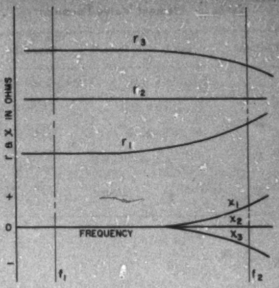

Fig. 2. Impedance of series arm z_a

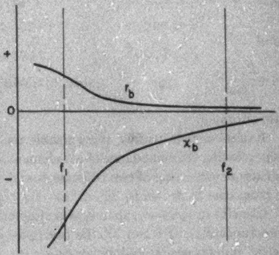

Fig. 3. Impedance of crossarm z_b

$$z_a = R_a + jx_a = \frac{a_0 + a_1 p}{1 + b_1 p} \tag{9}$$

where $p = j\omega$

The coefficients a_0, a_1 and b_1 are determined as follows:

At $\omega = \omega_1$

$$z_1 = R_1 + jx_1 = \frac{a_0 + ja_1\omega_1}{1 + jb_1\omega_1} \tag{10}$$

since

$x_1 \to 0$ as $\omega_1 \to 0$

$$a_0 = R_1 \tag{11}$$

At $\omega = \omega_2$

$$z_2 = R_2 + jx_2 = \frac{a_0 + ja_1\omega_2}{1 + jb_1\omega_2} \tag{12}$$

which is satisfied when

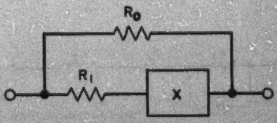

Fig. 4. General network of series arm z_a

Table I. Element Value Formulas

Element	Case I	Case II	Case III
	$b_1>\frac{a_1}{a_o}$	$b_1=\frac{a_1}{a_o}$	$b_1<\frac{a_1}{a_o}$
R_o	$\frac{a_1}{b_1}$	a_o	a_o
R_1	$\frac{a_oa_1}{a_1-a_ob_1}$	infinite	$\frac{a_1a_o}{b_1a_o-a_1}$
X	$L=\frac{a_1^2}{a_1+a_ob_1}$	infinite	$C=\frac{a_ob_1-a_1}{a_o^2}$

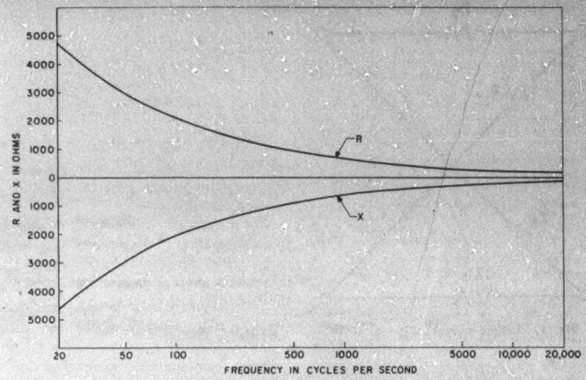

Fig. 6. Impedance of cable

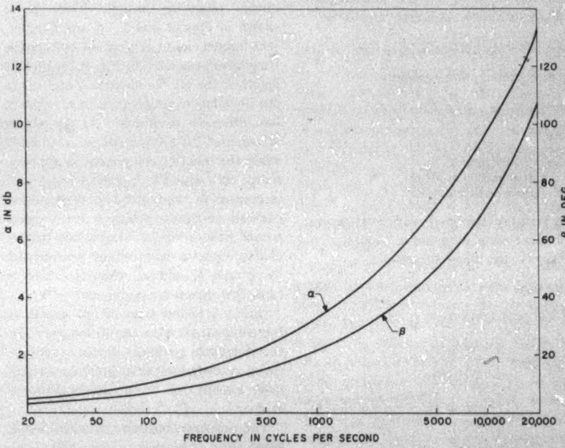

Fig. 7. Propagation constant of cable

$R_2-b_1x_2\omega_2=a_o$ and

$$x_2+b_1R_2\omega_2=a_1\omega_2 \tag{13}$$

Solving equations 13 for a_1 and b_1,

$$a_1=\frac{x_2^2+R_2(R_2-a_o)}{x_2\omega_2} \tag{14}$$

and

$$b_1=\frac{R_2-a_o}{x_2\omega_2} \tag{15}$$

are obtained.

Equation 9 is readily recognizable as representing the impedance of a 3-element structure consisting of two resistances and a reactance as shown in Fig. 4.

Clearly, if $a_1/a_o=b_1$, then z_2 is a simple resistance R_o. If $b_1>a_1/a_o$, the reactance is an inductance L and if $b_1<a_1/a_o$, the reactance is a capacitance C.

The element values may be computed from the formulas in Table I.

In Case III when $a_1=0$, $R_1=0$, $C=b_1/a_o$, and $R_o=a_o$.

In Case II $z_a=r=Rl/2$ where R is the d-c resistance per unit of length of cable. The condition which must exist for $x_a=0$ will now be developed.

Equation 5 can be written as

$$z_a=z_k\frac{\epsilon^{Pl}-1}{\epsilon^{Pl}+1}=z_k(m+jn) \tag{16}$$

From equations 1 and 16

$$z_a=(r_k-jx_k)(m+jn)=(r_km+x_kn)+j(r_kn-x_km) \tag{17}$$

In equation 17 the imaginary part becomes zero when

$$r_kn-x_km=0$$

$$\frac{x_k}{r_k}=\frac{n}{m} \tag{18}$$

then equation 17 becomes

$$z_a=r_km+x_kn=\frac{Rl}{2} \tag{19}$$

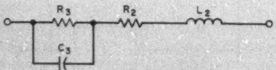

Fig. 5. General network of crossarm z_b

Since it is easy to show that $(m+jn)$ is proportional to (sinh $\alpha l+j$ sin βl), this equation holds when

$$\frac{\sin l\beta}{\sinh l\alpha}=\frac{x_k}{r_k} \tag{20}$$

B. SYNTHESIS OF z_b

Referring to Fig. 3, the impedance of the crossarm z_b is obviously composed of two parts; a resistance in parallel with a capacitor describing the low-frequency region plus a resistance and a small inductance connected in series to correct for the reactance at the higher frequencies.

The complete structure for z_b is shown in such as Fig. 5. Referring to the graphs in graphs in Fig. 3, at some low frequency such as f_1, the impedance

$z_b=r_1-jx_1$ and its admittance is (21)

$$Y_b=G+jB=\frac{r_1}{r_1^2+x_1^2}+j\frac{x_1}{r_1^2+x_1^2} \tag{22}$$

Now

$$R_3=\frac{1}{G}=\frac{r_1^2+x_1^2}{r_1} \tag{23A}$$

and

$$C_3 = \frac{B}{\omega_1} = \frac{x_1}{\omega_1(r_1^2 + x_1^2)} \tag{23B}$$

The resistance R_3 is generally more than the reactance of C_3 at f_1 so that at the higher frequency f_2, which may be 100 f_1, its effect is negligible. At f_2,

$$z_b = r_2 - jx_2 \tag{24}$$

so a resistance of value r_2 needs to be added in series. Now, x_2 is smaller than the reactance x_c of C_3 at f_2, and the difference must be made up by an inductance, that is

$$\frac{x_c - x_2}{\omega_2} = L_2 \tag{25}$$

when has a value of the order of a millihenry. x_2 is less than x_c when the distributed capacitance of the cable is fairly constant and decreases slightly with frequency and when the lengh of the cable is not too small.

To complete the design of the lattice structure, the conductance associated with physical capacitors should be included to obtain the correct performance of the network. If the silvered mica type[5] of capacitors are employed the effect of conductance is small in the frequency range up to 10,000 cps.

The complete schematics of the simulating networks for three cases are as shown in Fig. 8. The high resistance in the crossarm has been connected across the entire branch for convenience and the effect of this change is negligible throughout the frequency range.

Applications

Based on the preceding methods and on data represented by the curves of image impedance and propagation constants for a particular cable shown in Figs. 6 and 7 respectively, three simulating networks have been designed which are equivalent to lengths of 3,000, 4,229, and 6,000 feet. Network schematics with element values and the control frequencies are shown in Fig. 8. The conductances G_1 and G_2 are the inherent conductances of the capacitors C_1 and C_2 respectively.

Calculations were made on the performance of the networks and their deviations or design errors have been plotted in Figs. 9 and 10. In Fig. 9 are shown the reflection coefficients

$$\rho = \left|\frac{z_k - z_{in}}{z_k + z_{in}}\right|$$

in per cent versus frequency where z_{in}

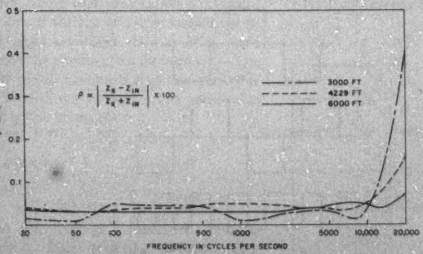

Fig. 9. Reflection coefficient: network versus cable

A More Stable 3-Phase Transistor-Core Power Inverter

W. E. JEWETT
ASSOCIATE MEMBER AIEE

P. L. SCHMIDT
ASSOCIATE MEMBER AIEE

THE 3-phase transistor-core power inverter described in this paper follows the trend away from mechanical devices toward lighter, more efficient, electronic equipment which, in most cases, are more reliable than the mechanical devices they replace. A single-phase transistor-core inverter has already replaced the mechanical multivibrator in one of our missile systems; it is only natural, then, for an electronic 3-phase inverter to follow as a power source for the 3-phase gyroscope motors which are part of the instrumentation in the same missile. This paper presents:

1. The need for a 3-phase inverter and discusses the reasons for the use of 3-phase gyroscope motors rather than d-c single-phase or 2-phase motors.
2. The waveshape characteristics of a 3-phase square-wave system and points out some of the system's limitations.
3. The operation of the 3-phase inverter which is an extended version of the one described by A. G. Milnes.[1]
4. The reasons for adding additional circuitry to Milnes' inverter to make it more stable over wide load ranges.

Need and Reasons for 3-Phase Inverter

Three-phase gyroscope motors are used in the guidance section of one of our missile systems because they offer distinct advantages over d-c, single-phase a-c, and 2-phase a-c motors. The d-c motors have commutators which get dirty and short, brushes which wear and sometimes make poor contact, and mechanical contacts which constantly make and break during the process of speed regulation. All of these mechanical features are highly undesirable from a reliability point of view. Single-phase a-c motors, in addition to coming up to rated speed rather slowly, require starting circuitry. As far as 2-phase motors are concerned, the gyroscope manufacturers consulted all agree that for the specified load conditions and required starting time (30 seconds) it would be extremely difficult for them to design a 2-phase motor which could match the performance of a 3-phase motor of comparable size and weight. They strongly recommended 3-phase motors. The reasons, then, for the choice of 3-phase motors are reliability and performance.

Once the 3-phase motors were decided upon, a static method of powering the motors had to be devised. This meant inverter-type circuitry which generates squarewaves. The question to be answered was: are the waveshape characteristics of a 3-phase square-wave system compatible with available motors which heretofore have been powered by a sine-wave system? The first logical thing to do was to look at these characteristics.

Waveshape Characteristics of 3-Phase Square-Wave System

Shown in Fig. 1 are the three phase voltages locked 120 degrees apart with respect to each other, the three line-to-line voltages obtained from the Y connection, and the third harmonic voltage which would cause circulating currents in the delta connection.

In a 3-phase system there are three possible generator connections: 1. Y with neutral; 2. Y with no neutral; and 3. delta.

Since the gyroscope motors are 3-wire there is no need to consider the first. The delta connection is prohibited by the fact that the third harmonic and its odd harmonics in each of the three phases add to give a voltage equal in magnitude to the phase voltage. If the delta were closed the windings would burn up. The only possible connection of this generator is Y with no neutral. The rms value of the line voltage is

$$E_{\text{rms}}\text{ line}=\sqrt{\frac{1}{\pi}\int_{0}^{2\pi/3}(2E_{\text{phase}})^{2}\,d\theta}$$
$$=1.63E_{\text{phase}} \quad (1)$$

The line voltage contains the fundamental, fifth, seventh, eleventh, thirteenth, etc., harmonics. The third and all its odd harmonics add out in the Y connection. A sine wave has been sketched through one of the line voltages showing the resemblance between the two. Thus, the motors are to be driven with a voltage other than a square wave. Actually, the waveshape of the phase voltage the motors experience depends upon whether they themselves are connected in the Y or delta configuration.

Figs. 2(A), (B), and (C) show the three phase currents of the motors if they are internally delta connected, and Fig. 2(D) shows one of the phase currents for the internal Y connection. Actually, Fig. 2 is for a resistive load. Figs. 3(A) and (B) show two of the phase currents for the internal delta connection and Fig. 3(C) shows one of the phase currents for the Y connection of the motors assuming they are inductive, which they are. For a 3-phase square-wave system, conclude the following:

1. The delta connection of the generator is not possible. This is somewhat disadvantageous as only one value of line voltage may be obtained.
2. For the Y connection of the generator, the line voltage and phase voltage waveshapes differ. The line and phase voltage

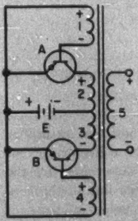

Fig. 4 (left). Schematic of basic d-c to a-c inverter using p-n-p transistors

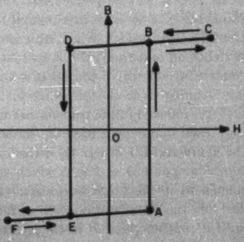

Fig. 5 (right). Typical hysteresis loop of inverter transformer core

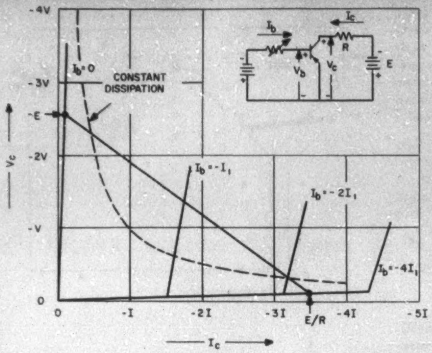

waveshapes differ at the load if it too is connected Y.

3. With a resistive 3-wire Y-connected load and a Y-connected generator, the phase voltages of the generator are square waves while the phase voltages of the load take the shape of the load-phase currents, Fig. 2(D). The rms values of these voltages are equal.

4. The current waveshapes are a function of load-power factor. They have high harmonic content for resistive loads, and they are smoother for inductive loads.

5. The line-to-line voltages of the Y-connected system bear some resemblance to a sine wave. This is because odd multiples of the third harmonic do not appear here.

Operation of 3-Phase Inverter

The inverter consists of three distinct parts: 1. three single-phase d-c to a-c inverters; 2. circuitry to synchronize these single-phase inverters; and 3. three power amplifiers which are driven in push-pull by the single-phase inverters. Each of these will be discussed in the order listed.

BASIC D-C TO A-C SINGLE-PHASE INVERTER

Because the basic inverter circuit has been widely discussed in the literature by Royer,[2] Uchrin and Taylor,[3] Van Allen,[4] and others, only a qualitative description of its action will be given here. Fig. 4 shows the inverter in its most simple form. Consider the instant when transistor *A* switches on and transistor *B* switches off connecting winding *2* to and disconnecting winding *3* from the battery. The voltages induced in the transformer windings then have polarities as shown in the figure and the flux in the transformer core is at point *A* of Fig. 5 which corresponds to its negative saturation value. The flux then increases linearly with time until it reaches point *B* of the hysteresis curve at which time the transformer core saturates in the positive direction. The time require for the transformer core to go from negative to positive saturation is derived from Faraday's law as:

$$t=\int_{-\phi\text{sat}}^{+\phi\text{sat}}\frac{N}{E}\,d\phi=\frac{2N\phi\text{ sat}}{E} \tag{2}$$

giving a frequency of

$$f=\frac{1}{2t}=\frac{E}{4N\phi\text{ sat}} \tag{3}$$

where

E = input voltage (Fig. 4)
N = number of primary turns either side of center tap
ϕ sat = saturation flux

When the transformer core saturates, point *B* of Fig. 5, the collector current increases to a value determined by the base current; thus, the flux in the core increases beyond its value at point *B* to some value at *C* which is slightly larger. At point *C* there is no further change in flux so all the induced voltages in the transformer windings fall to zero. The collector current now begins to fall to zero inducing voltages in the base windings *1* and *4*, which begin to drive transistor *B* into and transistor *A* out of conduction. The flux traverses the path from *C* to *D* quite rapidly and upon reaching point *D* the full battery voltage less some small transistor drop is applied to winding *3* of the transformer. The half cycle then repeats with transistor *B* conducting and transistor *A* nonconducting.

For the single-phase inverter to operate efficiently, the corners of the hysteresis loop must be quite sharp, and the base current only slightly higher than the value required for good output waveshape. Fig. 6 shows the transistor dissipation to be high in the switching region.

Fig. 9 (right). Two phases of power amplifier stage, and waveshape characteristic of line voltage

Excessive base current sends the transistor into a region where the dissipation is higher than it need be, and a core material having a hysteresis loop that is not sharp at the corners will keep the transistor in this region longer than is necessary.

SYNCHRONIZING CIRCUITRY
